Situations that predispose patients to lithium toxicity include sodium restriction, dehydration, vomiting, diarrhea, and drug interactions that decrease lithium clearance. Heavy exercise, sauna baths, hot weather, and fever can promote sodium loss. Patients should be cautioned to maintain adequate sodium and fluid intake (2.5–3 quarts [~2.5 to 3 L] per day of fluids) and to avoid the excessive use of coffee, tea, cola, and other caffeine-containing beverages and alcohol.

If lithium toxicity is suspected, the person should go to an emergency room to be monitored, and lithium should be discontinued.

Gastric lavage and intravenous fluids can be needed, and the patient should be monitored for fluid balance, renal and electrolyte status, and neurologic changes. In cases of overdose with sustained-release lithium products, the development and duration of toxicity can be prolonged. When lithium concentrations are above 3.5 to 4 mEq/L (mmol/L), intermittent hemodialysis (12 hours on and 12 hours off) can be started and continued until the lithium concentration is below 1 mEq/L (mmol/L) when taken 12 hours after the last dialysis. Hemoexchange is generally required when serum lithium levels are above 4 mEq/L (mmol/L) for patients on long-term treatment, and greater than 6 to 8 mEq/L (mmol/L) after acute poisoning. Rebound increases in serum lithium concentrations can occur 5 to 8 hours after dialysis, thus repeat dialysis can be needed.

**Drug–Drug Interactions** Thiazide diuretics, nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, angiotensin-converting enzyme inhibitors, and salt-restricted diets can elevate lithium levels. Neurotoxicity can occur when lithium is combined with carbamazepine, diltiazem, losartan, methylodopa, metronidazole, phenytin, and verapamil. Analgesics such as acetaminophen or aspirin and loop diuretics are less likely to interfere with lithium clearance. Caffeine and theophylline can enhance the renal elimination of lithium. Because lithium has no effect on hepatic metabolizing enzymes, it has fewer drug–drug interactions compared with carbamazepine, oxcarbazepine, and valproate.

**Dosing and Administration** Lithium dosing depends on the patient’s age and weight, tolerance to adverse effects, and the acuity of the illness. Dosing is generally titrated up to achieve steady-state serum lithium concentrations of 0.6 to 1.2 mEq/L (mmol/L). Lithium therapy is usually initiated with low to moderate doses (600 mg/day) for prophylaxis and higher doses (900–1,200 mg/day) for acute mania, using a 2- to 3-times daily dosing regimen. Immediate-release lithium preparations should be given in two or three divided daily doses, whereas extended-release products can be given once or twice daily. In clinical practice many clinicians dose the immediate-release and extended-release preparations once daily. It can be best to initially begin a patient on divided dosing, but once stabilized many patients are able to switch to once daily dosing without decompensating.

Lithium levels are considered to be at steady state at approximately day 5, and serum samples should be drawn 12 hours postdose. Once a desired serum concentration has been achieved, levels should be drawn in 2 weeks and then if stable every 3 to 6 months or as clinically indicated. Maintenance lithium serum concentrations are usually measured every 3 months, but can be adjusted to every 6 months for stabilized patients, and every 1 to 2 months for patients with frequent mood episodes. Lithium clearance rates increase by 50% to 100% during pregnancy and return to normal postpartum; thus lithium levels should be determined monthly during pregnancy and weekly the month before delivery. At delivery, rapid fluid changes can significantly increase lithium levels, thus a reduction to prepregnancy lithium doses and adequate hydration are recommended.

The recommended guidelines for baseline and routine laboratory testing for lithium are listed in Table 78–8. The 12-hour postdose lithium serum concentration can be 12% to 33% higher with extended-release preparations and lower with regular-release tablets with divided dosage schedules. The dose should be adjusted based on the steady-state serum concentration drawn 12 hours (~30 minutes) after the last dose. A therapeutic trial for outpatients should last a minimum of 4 to 6 weeks with lithium serum concentrations of 0.6 to 1.2 mEq/L (mmol/L). Acutely manic patients can require serum concentrations of 1 to 1.2 mEq/L (mmol/L), and some need up to 1.5 mEq/L (mmol/L) to achieve a therapeutic response. Although serum concentrations less than 0.6 mEq/L (mmol/L) are associated

**SECTION 7**

**Psychiatric Disorders**
with higher rates of relapse, some patients can do well at 0.4 to 0.7 mEq/L (mmol/L). For bipolar prophylaxis in elderly patients, serum concentrations of 0.4 to 0.6 mEq/L (mmol/L) are recommended because of increased sensitivity to adverse effects.2

### Anticonvulsants

In the 1980s, anticonvulsants were investigated for manic-depressive illness as the disorder had similar characteristics to episodic neurologic disorders such as epilepsy and migraines. Divalproex sodium (also known as sodium valproate) was marketed in 1995 for the acute treatment of mania in adults and is now the most prescribed mood stabilizer in the United States. Divalproex sodium is FDA approved only for the treatment of acute manic or mixed episodes; however, it is commonly used in clinical practice as maintenance monotherapy for bipolar disorder. Valproate also has limited data supporting its use in acute bipolar depression. Carbamazepine is commonly used for both acute and maintenance therapy. The only formulation approved in the United States for bipolar disorder is extended-release carbamazepine, although other formulations can be used. Some data support the use of oxcarbazepine, a 10-keto analogue of carbamazepine, in the treatment of bipolar disorder; however, it is not approved for the treatment of bipolar disorder in the United States. Valproate, carbamazepine, and oxcarbazepine each have a wide range of neurologic, gastrointestinal, electrolyte, and hematologic adverse effects that requires regular assessment and routine blood work.

Lamotrigine is FDA approved for the maintenance treatment of bipolar I disorder. Lamotrigine add-on or monotherapy has been used for treatment-refractory bipolar depression, but may not be supported by data from numerous clinical trials. Lamotrigine is associated with hypersensitivity reactions and rare life-threatening skin rashes and requires slow dosage titration.2

### Valproate Sodium and Valproic Acid

The exact mechanism of action of valproic acid is not known. Valproic acid is a branched chain fatty acid and was originally used as an organic solvent before it was discovered in the 1960s to have anticonvulsant properties. Valproate has antimigraine, mood-stabilizing, and antiaggressive effects. In 1995, the enteric-coated formulation divalproex sodium (valproate) was approved for the acute treatment of mania. Several controlled studies have shown valproate to be as effective as lithium and olanzapine in patients with pure mania, and it can be more effective than lithium in certain subtypes of bipolar disorder (e.g., rapid cycling, mixed states, bipolar disorder with comorbid substance abuse). Placebo- and lithium-controlled and open

</table>

- SGA: Screen for drug abuse and serum pregnancy.
- Complete blood cell count (CBC) with differential and platelets.
- Fasting glucose, serum lipids, weight.
- Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.
- Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.
- Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.
- Serum sodium.
- Rash, acne, alopecia.
- Second-generation antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy, cases of hyperlipidemia and diabetes reported.
- Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (e.g., CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are <100,000/mm³ (<100 × 10⁹/L); if white blood cell (WBC) count is <3,000/mm³ (<3 × 10⁹/L) or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hypovolemia. Carbamazepine interferes with some pregnancy tests.
- Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer’s guidelines. Serious dermatologic reactions have occurred within 2–8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.
- Lithium: Obtain baseline electrocardiogram for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2–3 months during the first 6 months, then every 6–12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume >1 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6–12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1–2 months until thyroid function indices are within normal range, then monitor every 3–6 months.
- Oxcarbazepine: Hyponatremia (serum sodium concentrations <125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (e.g., diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (e.g., confusion, headache, lethargy, and malaise). Hyponatremia reactions have occurred in approximately 25%–30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.
- Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3–6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are <100,000/mm³ (<100 × 10⁹/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

studies report that valproate reduces or prevents recurrent manic, depressive, and mixed episodes.\textsuperscript{2,3,10} Although valproate is not approved for bipolar disorder in children and adolescents, studies suggest that it is effective and well tolerated.\textsuperscript{10,30}

Giving lithium, carbamazepine, antipsychotics, or benzodiazepines with valproate can augment its antimanic effects. The addition of valproate to lithium can have synergistic effects in treatment-refractory rapid cycling and mixed states, and the combination has demonstrated efficacy in maintenance therapy for bipolar I disorder.\textsuperscript{27} Combinations of valproate and carbamazepine can have synergistic effects, but the potential drug interactions make blood level monitoring of both agents essential.\textsuperscript{10} Adding adjunctive SGAs to valproate can be effective for breakthrough mania or if there is incomplete or partial response to monotherapy. Clozapine, olanzapine, and quetiapine can increase the risk of sedation and weight gain when combined with valproate. The combination of valproate and lamotrigine can be effective, but there is an increased risk of rashes, ataxia, tremor, sedation, and fatigue.\textsuperscript{34,36}

**Adverse Effects** The most frequent dose-related adverse effects with valproate are gastrointestinal complaints (anorexia, nausea, indigestion, vomiting, mild diarrhea, and flatulence), fine hand tremors, and sedation.\textsuperscript{2,10,34} The gastrointestinal complaints are usually transient, but giving the medication with food, using lower initial doses with gradual increases in doses, or switching to divalproex sodium extended-release tablets can minimize them.\textsuperscript{2,10} Reduction of the dose or the addition of a β-blocker can alleviate tremors, and giving the total daily dose at bedtime can minimize daytime sedation.\textsuperscript{2,10}

Other adverse effects of valproate include ataxia, lethargy, alopecia, changes in the texture or color of hair, pruritus, prolonged bleeding because of inhibition of platelet aggregation, transient increases in liver enzymes, and hyperammonemia.\textsuperscript{10,34} Increased appetite and weight gain occurs in approximately 50% of patients on long-term valproate therapy. Thrombocytopenia can occur at higher doses, and patients should be monitored for bleeding and bruising. Lowering the valproate dose can restore platelet counts to normal levels.\textsuperscript{2} Fatal necrotizing hepatitis is a rare idiosyncratic, non–dose-related adverse effect that has occurred in children with epilepsy receiving multiple anticonvulsants.\textsuperscript{10,34} A life-threatening hemorrhagic pancreatitis has been reported in both children and adults.\textsuperscript{2,10,34} An in-depth discussion of adverse effects can be found in Chapter 65.

**Drug–Drug Interactions** A summary of drug–drug interactions for valproate can be found in Chapter 65.

**Dosing and Administration** For healthy inpatient adults with acute mania, the initial starting dosage of valproate is typically 20 mg/kg/day in divided doses over 12 hours. The daily dose is adjusted by 250 to 500 mg every 1 to 3 days based on clinical response and tolerability. Maximum recommended dosing is 60 mg/kg/day (see Table 78–7).\textsuperscript{2,10,34} For outpatients who are hypomanic or euthymic, or for elderly patients, the initial starting dose is generally lower (5–10 mg/kg/day in divided doses) and gradually titrated to avoid adverse effects. Once an optimal dose has been achieved, the total daily dose can be given twice daily or at bedtime if tolerated.\textsuperscript{2,10,34} Extended-release divalproex can be administered once daily, but bioavailability can be 15% lower than immediate-release products, thus requiring slightly higher doses.\textsuperscript{2} In clinical practice patients with bipolar disorder who are stable can be switched between formulations without having to change the dose. This is not the case for patients with seizure disorder.

Recommended baseline and routine laboratory tests for valproate are listed in Table 78–8. Although therapeutic serum concentrations of valproic acid have not been established in bipolar disorder, most clinicians use the anticonvulsant therapeutic serum range of 50 to 125 mcg/mL (345 to 866 μmol/L) taken 12 hours after the last dose.\textsuperscript{2,10} In one study patients with valproate levels greater than 94.1 mcg/mL (651 μmol/L) had greater efficacy for bipolar mania.\textsuperscript{57} Patients with cyclothymia or mild bipolar II disorder can have a therapeutic response to lower doses and blood levels, whereas some patients with a more severe form of bipolar disorder can require up to 150 mcg/mL (1,040 μmol/L). Serum valproic acid levels are most useful when assessing for compliance and toxicity.

---

**Carbamazepine** Carbamazepine, a dibenzazepine derivative, is structurally related to tricyclic antidepressants.\textsuperscript{10} The precise mechanism of action of carbamazepine in affective disorders remains to be elucidated.\textsuperscript{12} Carbamazepine is not a first-line agent for bipolar disorder, and is generally reserved for lithium-refractory patients, rapid cyclers, or for mixed states.\textsuperscript{2,10} Carbamazepine has acute antimanic effects comparable to lithium and chlorpromazine, but its long-term effectiveness is unclear.\textsuperscript{10,39} One comparison trial in hospitalized manic patients indicated that carbamazepine was less effective and needed more rescue adjunctive medications than valproate.\textsuperscript{2} Other comparison studies with lithium have reported carbamazepine to be less effective than lithium for maintenance therapy.\textsuperscript{2} In a double-blind, placebo-controlled crossover study and in an open study, carbamazepine showed efficacy in the treatment of bipolar depression.\textsuperscript{2,10} Studies with treatment-refractory patients have reported that carbamazepine has both acute and long-term prophylactic effects.\textsuperscript{3,10} A gradual loss of efficacy over time (similar to lithium and valproate) has been reported in some patients.\textsuperscript{3,10}

The combination of carbamazepine with lithium, valproate, and antipsychotics is often used for treatment-resistant patients experiencing a manic episode.\textsuperscript{10} Carbamazepine plus olanzapine was not found to be more effective than carbamazepine alone in the treatment of acute mania or mixed episodes.\textsuperscript{41} Carbamazepine increases the hepatic metabolism of antidepressants, anticonvulsants, and antipsychotics; thus dosage increases can be necessary (see drug–drug interactions).\textsuperscript{10,39} Calcium channel blockers (e.g., verapamil and diltiazem) increase carbamazepine blood levels; thus combination therapy should be closely monitored.\textsuperscript{39} The combination of carbamazepine with nizogepine for treatment-refractory bipolar illness can have potential benefit.\textsuperscript{39}

**Adverse Effects** A summary of adverse effects for carbamazepine can be found in Chapter 65. Acute overdoses of carbamazepine are potentially lethal, and serum levels above 15 mcg/mL (63 mmol/L) are associated with ataxia, choreiform movements, diplopia, nystagmus, cardiac conduction changes, seizures, and coma.\textsuperscript{2} Gastric lavage, hemoperfusion, and symptomatic treatment are recommended for the management of carbamazepine toxicity.

**Drug–Drug Interactions** Carbamazepine significantly induces the hepatic cytochrome P450 isoenzyme 3A4 and to a lesser degree 1A2, 2C9/10, and 2D6, which increases the metabolism of many
Carbamazepine is metabolized to an active 10,11-epoxide metabolite, thus medications that inhibit 3A4 isoenzymes can result in carbamazepine toxicity (e.g., cimetidine, diltiazem, erythromycin, fluoxetine, fluvoxamine, isoniazid, itraconazole, ketoconazole, nefazodone, propoxyphene, and verapamil).\textsuperscript{2,3,10,58} When carbamazepine is combined with valproate, the carbamazepine dose should be reduced because valproate displaces carbamazepine from protein-binding sites, thus increasing free levels.\textsuperscript{10} Combining clozapine and carbamazepine is not recommended because of the possibility of bone marrow suppression with both agents.\textsuperscript{10}

**Dosing and Administration**

During an acute manic episode in most hospitalized patients, carbamazepine can be started at 400 to 600 mg/day in divided doses with meals and increased by 200 mg/day every 2 to 4 days up to 10 to 15 mg/kg per day. In outpatients the initial dose of carbamazepine should be lower and titrated gradually in order to avoid adverse effects. In clinical practice many patients are able to tolerate once daily dosing of carbamazepine once their mood episode has stabilized. The dose of carbamazepine should be gradually increased until response is achieved or there is evidence of toxicity. During the first month of therapy, serum concentrations of carbamazepine may be effected due to autoinduction of cytochrome P450 3A4 enzymes.\textsuperscript{18}

Carbamazepine serum levels are usually obtained every 1 to 2 weeks during the first 2 months, and then every 3 to 6 months during maintenance therapy. Serum levels should be drawn 10 to 12 hours after the dose (trough levels) and at least 4 to 7 days after a dosage change. Although there is no correlation between carbamazepine serum concentration and degree of antimanic or antidepressant response, most clinicians attempt to maintain levels between 6 and 10 mcg/mL (25 and 42 mmol/L) (although some treatment-resistant patients can require serum concentrations of 12–14 mcg/mL [51–59 mmol/L]). Recommended baseline and routine laboratory tests for carbamazepine are listed in Table 78–8.

**Oxcarbazepine**

Oxcarbazepine, a 10- keto analog of carbamazepine, blocks voltage-sensitive sodium channels, modulates voltage-activated calcium currents, and increases potassium conductance.\textsuperscript{20} Initial trials suggested oxcarbazepine has mood-stabilizing effects similar to those of carbamazepine, with the advantages of milder adverse effects, no autoinduction of liver enzymes, and potentially fewer drug interactions.\textsuperscript{2} There are currently less data supporting the use of oxcarbazepine than carbamazepine in the treatment of bipolar disorder. The APA treatment guidelines recommend the use of oxcarbazepine in any situation where one would use carbamazepine. However, many clinicians prefer to use oxcarbazepine only after a patient has failed treatment with carbamazepine or because of an adverse reaction or side effects. Genuine debate exists regarding drug interactions, side effects, and rates of hyponatremia with oxcarbazepine.

**Adverse Effects**

Oxcarbazepine has dose-related adverse effects of dizziness, sedation, headache, ataxia, fatigue, vertigo, abnormal vision, diplopia, nausea, vomiting, and abdominal pain.\textsuperscript{20} In one study, hyponatremia was reported to occur in patients taking oxcarbazepine and carbamazepine at rates of 29.9% and 13.5%, respectively.\textsuperscript{61} Severe hyponatremia (sodium less than or equal to 128 mEq/L [mmol/L]) was reported by Dong and coworkers as 12.4% and 2.8% of patients for oxcarbazepine and carbamazepine, respectively.\textsuperscript{61} An in-depth discussion of adverse effects can be found in Chapter 65.

**Drug–Drug Interactions**

Oxcarbazepine, a cytochrome P450 2C19 enzyme inhibitor and a 3A3/4 enzyme inducer, has the potential for causing drug interactions.\textsuperscript{62} Oxcarbazepine induces the metabolism of oral contraceptives, thus alternative contraceptive measures are required.\textsuperscript{3,62}

**Dosing and Administration**

Initial dosing is usually 150 to 300 mg twice daily, and daily doses can be increased by 300 to 600 mg every 3 to 6 days up to 1,200 mg/day in divided doses (with or without food).\textsuperscript{60}

**Lamotrigine**

Lamotrigine blocks voltage-sensitive sodium channels, modulates or decreases glutamate and aspartate release, and has antikindling properties.\textsuperscript{1,12,13,58}

**Efficacy**

The effectiveness of lamotrigine for the maintenance treatment of bipolar I disorder in adult patients was established in two multicenter double-blind, placebo-controlled studies.\textsuperscript{2} Doses of 200 mg/day were more effective than lower doses, and there were no advantages to using 400 mg/day. Lamotrigine has both antidepressant and mood-stabilizing effects, it may have augmenting properties when combined with lithium or valproate, and has low rates of switching patients to mania.\textsuperscript{58,64} Although lamotrigine is less effective for acute mania compared to standard mood stabilizers, it may be beneficial in the maintenance therapy of treatment-resistant bipolar I and II disorders, in rapid-cycling dysthmic mania, and in mixed states.\textsuperscript{2,58} Lamotrigine seems to be most effective for the prevention of bipolar depression, therefore clinically it is often used in the treatment of patients with bipolar II. There are case reports of possible lamotrigine induced mania when added to lithium, carbamazepine, and valproate.\textsuperscript{65} In each of the cases reported, the patients had depressive mood symptoms or rapid mood changes requiring additional therapy.\textsuperscript{65}

**Adverse Effects**

Common adverse effects include headache, nausea, dizziness, ataxia, diplopia, drowsiness, tremor, rash, and pruritus.\textsuperscript{58,63} Approximately 10% of patients in premarketing clinical trials developed a maculopapular rash and required discontinuation of therapy.\textsuperscript{56,63} Although most rashes are self-limiting and resolve with continued treatment, some cases progressed to life-threatening conditions such as Stevens-Johnson syndrome. The incidence of rash appears to be greatest with coadministration of valproate, with higher than recommended initial doses, and with rapid dose escalation.\textsuperscript{61} Patients should be warned about the rash, and the need for discontinuing lamotrigine if the rash is diffuse, involves mucosal membranes, and is accompanied by a fever or sore throat. For an in-depth discussion of the adverse effects of lamotrigine, see Chapter 65.

**Drug–Drug Interactions**

Valproate decreases the clearance of lamotrigine (i.e., more than doubles the half-life), and lamotrigine must be administered at a reduced dosage (approximately half the standard dose).\textsuperscript{56,63} For an in-depth discussion of drug–drug interactions with lamotrigine, see Chapter 65.

**Dosing and Administration**

For the maintenance treatment of bipolar disorder, the usual dosage range of lamotrigine is 50 to 300 mg/day. The target dose is generally 200 mg/day (100 mg/day in combination with valproate and 400 mg/day in combination with carbamazepine).\textsuperscript{56,63} For patients not taking medications that affect lamotrigine’s clearance, the dose is 25 mg/day for the first 2 weeks of therapy, 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and 200 mg/day for week 6 and beyond.\textsuperscript{2,56,63} Patients who stop lamotrigine therapy for more than a few days should be restarted on the recommended dosage escalation titration schedule.

**Antipsychotics**

First-generation antipsychotics that block DA\textsubscript{1} receptors and SGAs that block both DA\textsubscript{2} and 5-HT\textsubscript{1A} receptors are used to decrease DA activity in the treatment of mania and mixed states. First- and second-generation antipsychotics such as aripiprazole, haloperidol, olanzapine, quetiapine, risperidone, and ziprasidone are effective as monotherapy or adjunctive therapy in the treatment of acute mania.\textsuperscript{66} Controlled studies in acute mania with lithium or valproate plus an
antipsychotics suggest greater efficacy with combination therapies compared with any of these agents alone.2,4,6 First-generation antipsychotics (e.g., chlorpromazine and haloperidol) are effective in up to 70% of patients with acute mania, particularly those with psychosis and psychomotor agitation. Second-generation antipsychotics have demonstrated similar efficacy for the treatment of acute mania associated with agitation, aggression, and psychosis.2,4,6

Treating acute bipolar depression is very challenging, and some antipsychotics may play a useful role. Quetiapine has four large randomized controlled trials supporting its use as a monotherapy treatment option for bipolar depression.41 The fluoxetine/olanzapine combination also has efficacy data in treating bipolar depression.

Long-term safety of antipsychotics as monotherapy or as an adjunctive therapy for bipolar maintenance treatment still needs to be evaluated.2,4,27,41 Risks versus benefits must be weighed due to the long-term adverse effects (e.g., obesity, type 2 diabetes, hyperlipidemia, hyperprolactinemia, and tardive dyskinesia) antipsychotics may cause.46,48 Aripiprazole, olanzapine, and risperidone long-acting injection are effective monotherapy options for maintenance treatment in bipolar disorder.41 Some data reported in abstract form support quetiapine for maintenance treatment. First-generation depot antipsychotics (e.g., haloperidol decanoate, fluphenazine decanoate) can have a place in maintenance treatment of bipolar disorder in patients who are noncompliant or treatment resistant.4

Clozapine monotherapy has acute and long-term mood-stabilizing effects in refractory bipolar disorder, including conditions with mixed mania and rapid cycling, but requires regular white blood cell monitoring for agranulocytosis.5,10,16

**Adverse Effects** A summary of adverse effects for antipsychotics can be found in Chapter 76.

**Drug–Drug Interactions** A summary of drug interactions with antipsychotics can be found in Chapter 76.

**Dosing and Administration** For acute mania, higher initial doses of antipsychotics can be required (e.g., olanzapine 20 mg/day in hospitalized patients). Once acute mania is controlled (usually within 7–28 days), the antipsychotic can be gradually tapered and discontinued, and the patient maintained on the mood stabilizer alone.

**Monitoring** Recommendations for baseline and routine laboratory testing for patients receiving carbamazepine, lamotrigine, lithium, oxcarbazepine, SGAs, and valproate are found in Table 78–8.

### Alternative Medication Treatments

#### Benzodiazepines

Weighing the risk to benefit ratio, high potency benzodiazepines such as clonazepam and lorazepam are commonly used as an alternative to or in combination with antipsychotics when patients are experiencing acute mania, agitation, anxiety, panic, and insomnia, or cannot take mood stabilizers (e.g., during the first trimester of pregnancy).2,4,10,70 Lorazepam is available for intramuscular injection and is useful in the acute management of agitation. Benzodiazepines cause minimal adverse effects compared with antipsychotics, and at higher doses, rapidly sedate agitated patients.2 Benzodiazepines can cause central nervous system depression, sedation, cognitive and motor impairment, dependence, and withdrawal reactions. When no longer required, benzodiazepines should be gradually tapered and discontinued to avoid withdrawal symptoms.

**Antidepressants** For many years antidepressants were recommended as adjunctive therapy for acute bipolar depression. Recent data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) suggest that adjunctive antidepressants may be no better than placebo for acute bipolar depression when combined with mood stabilizers.71 Controversy exists concerning the use of antidepressants, and many clinicians consider them third line in treating acute bipolar depression, except in patients with no history of severe and/or recent mania or potentially in bipolar II patients.72 The concern of mood switching with the use of antidepressants is valid, although not common. Data show that the rates of mood switch with SSRIs is around 3.8%, similar to placebo when combined with mood stabilizers. The rate of mood switch with dual acting agents (e.g., TCAs or venlafaxine) is higher, and thus these agents should be used with caution.72,73 It is very important that before initiating therapy with an antidepressant, the patient should be on a therapeutic dosage or blood level of a primary mood stabilizer.74 Patients who have a history of mania after a depressive episode or who have frequent cycling should be treated cautiously with antidepressants.2,3 In general, the antidepressant should be gradually withdrawn 2 to 6 months after remission, and the patient maintained on a mood-stabilizing agent.26,74 For more information, see Chapter 77 for comparisons among antidepressants.

#### Calcium Channel Antagonists

Calcium channel antagonists inactivate voltage-sensitive calcium channels, thus inhibiting neurotransmitter synthesis and release and neuronal signal transmission.19,12 Verapamil, a nondihydropyridine, has demonstrated mood-stabilizing properties in some studies, but negative results were found in other trials.2,3,10,73 Nimodipine, a dihydropyridine, can be more effective than verapamil for rapid-cycling bipolar disorder because of its anticonvulsant properties, high lipid solubility, and good penetration into the brain.2,3,10,12,13 Calcium channel blockers are generally well tolerated, and the most common adverse effects are bradycardia and hypotension. These are seldom used in everyday clinical practice.
Newer Anticonvulsants Third-generation anticonvulsants have been investigated for treating bipolar disorder with the hope that a different mechanism of action would be beneficial for mood stabilization. Gabapentin, levetiracetam, tiagabine, topiramate, and zonisamide have negative or limited positive data supporting their use in bipolar disorder. Topiramate has been used as an add-on weight-reduction medication, but there are no randomized controlled trials supporting its use in bipolar disorder.86

Novel Agents and Dietary Intake Disturbances in 5-HT neurotransmission secondary to inadequate dietary L-tryptophan or abnormalities in tryptophan hydroxylase, 5-HT transporters, and 5-HT receptors was implicated in the pathophysiology of manic-depressive illness as early as 1958.87 Low 5-HT activity may be a trait marker for bipolar disorder.21 If available 5-HT is low, the synthesis and secretion of melatonin can be disrupted, thus causing circadian rhythm changes.10 Acute tryptophan depletion has been shown to reverse the antidepressant effects of 5-HT reuptake inhibitors in depressed patients in remission, but may not negatively affect mood in lithium-stabilized bipolar patients.77 Randomized controlled studies of L-tryptophan or 5-hydroxytryptophan have shown positive results in the acute treatment and prophylaxis of bipolar disorder.10 Because 5-HT synthesis in the brain is dependent on dietary L-tryptophan intake, the importance of adequate and regular ingestion of animal-derived protein should be discussed with patients.10 A dietary deficiency in essential fatty acids (found in certain fish oils and flaxseed oil that contains α-linolenic acid) has been proposed as a potential cause of mood disorders.78,79 Omega-3 fatty acids have been shown to suppress neuronal pathways and inhibit kindling processes by several mechanisms (e.g., inhibition of phosphatidylinositol and G-protein secondary messengers and blocking L-type calcium channels). Seafood and fish are rich dietary sources of omega-3 essential fatty acids, specifically docosahexaenoic acid and eicosapentaenoic acid.79 Omega-3 fatty acids may have more antidepressant than antimanic effects.80 Data reported by Keck and colleagues for bipolar depression and rapid cycling did not support the use of eicosapentaenoic acid.80 The data supporting the use of omega-3 fatty acids is controversial and needs to be further evaluated.

Special Populations

The approach for treating bipolar disorder in special populations (e.g., comorbid medical or psychiatric disorders, pregnancy, or breastfeeding) can vary among clinicians. Patients with comorbid medical conditions or concomitant substance abuse, those older than 65 years of age, and pregnant patients can require different treatment approaches. Women have a high risk of relapse postpartum; therefore, prophylaxis with mood stabilizers is recommended immediately postpartum to decrease the risk of relapse.62

Prophylactic medications such as lithium or valproate can prevent postpartum episodes in women with bipolar disorder.2 Pharmacotherapy during pregnancy is complicated, and the risk-to-benefit ratio must be weighed. Infants whose mothers took lithium during the first trimester of pregnancy may have a lower incidence of cardiovascular defects (particularly Ebstein anomaly) than was previously thought.2,40 Current estimates of this malformation during the first trimester are estimated between 1:1,000 and 1:2,000.62 Lithium freely crosses the placenta and is found in equal concentrations in maternal and fetal blood.40 When lithium is used during pregnancy, it should be tapered down to the lowest effective dose necessary to decrease the risk of relapse. Lithium can cause “floppy” infant syndrome (e.g., low Apgar scores, lethargy, hypotonia, bradycardia, cyanosis, shallow respiration, and poor sucking), hypothyroidism, and nontoxic goiters. Milk concentrations of lithium during the first trimester of pregnancy may have a lower risk of fetal abnormalities.88 Use of antipsychotics in catatonia should be minimized because of the risk of adverse effects.87 Treatment of catatonia also varies from standard treatment in that mood stabilizers and antipsychotics have minimal effect. Catatonic features such as mutism, motor excitement, stereotypic movements, waxy flexibility, negativism, echopraxia, and echolalia are best treated with benzodiazepines, specifically lorazepam. The use of antipsychotics in catatonia should be minimized because of an increased risk of neuroleptic malignant syndrome. ECT is also a treatment option in this patient population.

PHARMACOECONOMIC CONSIDERATIONS

Bipolar disorder is one of the leading causes of chronic disability worldwide and shares characteristics of both major depressive disorder and schizophrenia.1 Bipolar disorder is primarily treated in the public mental health sector, and a majority of patients receive lifelong disability coverage because of compromised functioning.3
The total cost to society for bipolar disorder is enormous and is exceeded only by the costs for treating individuals with schizophrenia. It was estimated, more than a decade ago, that the total annual economic impact of bipolar disorder in the United States was approximately $45 billion per year.

**EVALUATION OF THERAPEUTIC OUTCOMES**

The establishment and maintenance of a therapeutic alliance with a clinician is essential in monitoring a patient’s psychiatric status and safety; enhancing treatment adherence; promoting good nutrition, sleep, and exercise; identifying stressors; recognizing new mood episodes; and minimizing adverse reactions and drug interactions. Patients who have a partial response or nonresponse to established bipolar therapies should be reassessed for an accurate diagnosis, concomitant medical or psychiatric conditions, and medications or substances that exacerbate mood symptoms. Nonadherence to medication treatment, delusional symptoms, alcohol or substance abuse, rapid cycling, or mixed states are often associated with poorer treatment outcomes.

The evaluation of therapeutic outcomes for bipolar disorder requires regular monitoring by a clinician. More frequent office visits, telephone calls, and intensive outpatient programs are first-line strategies to prevent hospitalization during the acute treatment phase of a manic or depressive episode. Patients (and family members if needed) should be actively involved with their treatment and help to monitor target symptoms, efficacy of treatment, treatment adherence, and adverse effects.

Standardized rating scales for mania and depression are used to measure severity and changes in symptoms in clinical trials (e.g., Young Mania Rating Scale, brief bipolar disorder symptoms scale, Hamilton Rating Scale for Depression, and Montgomery-Åsberg Depression Rating Scale). Patient-rated life mood charts, a timeline of stressful life events, and a graphic display of sleep patterns are helpful in recognizing early symptoms of mood episodes and in documenting patterns and lengths of episodes. A mood disorder questionnaire, a 13-item self-reported screening tool, was developed to differentiate bipolar disorder from other mood disorders (www.dbsalliance.org/questionnaire/screening_intro.asp). Health-related quality of life scales such as the Short Form (SF)-36 and the Psychological General Well-Being Scale have been recommended to assess the quality of life in individuals with bipolar disorder.

SECTION 7

Anxiety Disorders I: Generalized Anxiety, Panic, and Social Anxiety Disorders

SARAH T. MELTON AND CYNTHIA K. KIRKWOOD

KEY CONCEPTS

1. The long-term goal in generalized anxiety disorder (GAD) is remission with minimal or no anxiety symptoms and no functional impairment.

2. Antidepressants are the agents of choice for the management of GAD.

3. Antidepressants have a lag time of 2 to 4 weeks or longer before antianxiety effects occur in GAD.

4. When monitoring the effectiveness of antidepressants in panic disorder, it is important to allow an adequate amount of time (8 to 12 weeks) to achieve full therapeutic response.

5. Clonazepam and extended-release alprazolam are alternatives to immediate-release alprazolam for patients with panic disorder having breakthrough panic symptoms at the end of a dosing interval.

6. The optimal duration of panic therapy is unknown; 12 to 24 months of pharmacotherapy is recommended before gradual drug discontinuation over 4 to 6 months is attempted.

7. Social anxiety disorder (SAD) is a chronic long-term illness requiring extended therapy. After improvement, at least a 1-year medication maintenance period is recommended.

8. The selective serotonin reuptake inhibitors or venlafaxine are considered first-line pharmacotherapy for SAD.

9. An adequate trial of antidepressants in generalized social anxiety disorder lasts at least 8 weeks, and maximal benefit may not be seen until 12 weeks.

10. The three principal domains in which improvement should be observed in generalized social anxiety disorder are symptoms, functionality, and well-being.

Anxiety is an emotional state commonly caused by the perception of real or perceived danger that threatens the security of an individual. It allows a person to prepare for or react to environmental changes. Everyone experiences a certain amount of nervousness and apprehension when faced with a stressful situation. This is an adaptive response and is transient in nature.

Anxiety can produce uncomfortable and potentially debilitating psychologic (e.g., worry or feeling of threat) and physiologic arousal (e.g., tachycardia or shortness of breath) if it becomes excessive. Some individuals experience persistent, severe anxiety symptoms and possess irrational fears that significantly impair normal daily functioning. These persons often suffer from an anxiety disorder.¹

Anxiety disorders are among the most frequent mental disorders encountered in clinical practice. Healthcare professionals often mistake anxiety disorders for physical illnesses, and only 23% of patients receive appropriate treatment.² Failure to diagnose and manage anxiety disorders results in negative outcomes including overuse of healthcare resources, increased morbidity, and mortality.³ Individuals with anxiety disorders develop cardiovascular, cerebrovascular, gastrointestinal, and respiratory disorders at a significantly higher rate than the general population.⁴

To treat anxiety appropriately, the clinician must make a reliable diagnosis. It is essential that the distinction between short-term symptoms of anxiety and anxiety disorders be understood. Common or situational anxiety is a normal response to a stressful circumstance. Although symptoms can be severe, they are temporary and usually last no more than 2 or 3 weeks. Although short-term, as-needed treatment with an anxiolytic agent such as a benzodiazepine is common and can provide some symptomatic relief, prolonged drug therapy is not recommended.⁵

EPIDEMIOLOGY

Anxiety disorders, as a group, are the most commonly occurring psychiatric disorders. According to the National Comorbidity Survey Replication on the prevalence, severity, and comorbidity estimates of mental disorders in the United States, the most recent 1-year prevalence rate for anxiety disorders was 19.1% in persons aged 18 years and older. Specific phobias were the most common anxiety disorder, with a 12-month prevalence of 9.1%. The 1-year prevalence of generalized anxiety disorder (GAD) was 2.7%, that of panic disorder was 2.7%, and that of social anxiety disorder (SAD) was 7.1%.⁶

In general, anxiety disorders are a group of heterogeneous illnesses that develop before age 30 years and are more common in women, individuals with social issues, and those with a family history of anxiety and depression. Patients often develop another anxiety disorder, major depression, or substance abuse.¹⁻³ The clinical picture of mixed anxiety and depression is much more common than an isolated anxiety disorder.²

ETIOLOGY

The differential diagnosis of anxiety disorders includes medical and psychiatric illnesses and certain drugs.² Hypotheses on the etiology of anxiety disorders are based on interactions between a combination of
factors including vulnerability (e.g., genetic predisposition and early childhood adversity) and stress (e.g., occupational and traumatic experience). The vulnerability may be associated with genetic factors and neurobiological adaptations of the central nervous system (CNS).7

**MEDICAL DISEASES ASSOCIATED WITH ANXIETY**

Anxiety symptoms are an inherent part of the initial clinical presentation of several diseases, thus complicating the distinction between anxiety disorders and medical disorders.2,4 Anxiety disorders are strongly and independently associated with chronic medical illness, low levels of physical health-related quality of life (QOL), and physical disability.7 If anxiety symptoms are secondary to a medical illness, they usually will subside as the medical situation stabilizes. However, the knowledge that one has a physical illness can trigger anxious feelings and further complicate therapy. Persistent anxiety subsequent to a physical illness requires further assessment for an anxiety disorder. Common somatic symptoms of anxiety that frequently present in medical disorders include abdominal pain, palpitations, tachycardia, sweating, flushing, tremor, chest pain or tightness, and shortness of breath. Although less specific, symptoms of muscle tension, headache, and fatigue are also common manifestations of anxiety. Medical disorders most closely associated with anxiety are listed in Table 79–1.2,4,8–10

**PSYCHIATRIC DISEASES ASSOCIATED WITH ANXIETY**

Anxiety can be a presenting feature of several major psychiatric illnesses. Anxiety symptoms are extremely common in patients with mood disorders, schizophrenia, dementia, and substance use disorders. Most psychiatric patients will have two or more concurrent psychiatric disorders (comorbidity) within their lifetime.6 It is important to diagnose and treat all comorbid psychiatric conditions in patients with anxiety disorders.

**DRUG-INDUCED ANXIETY**

Drugs are a common cause of anxiety symptoms (Table 79–2). Anxiety occurs during the use of CNS-stimulating drugs in a dose-dependent manner, but ingestion of minimal amounts can result in marked anxiety, including panic attacks, in some individuals. The onset of drug-induced anxiety is usually rapid after the initiation of therapy. A thorough medication history evaluating for a recent drug or dosage change is important to rule out a drug-induced etiology for the anxiety.

Data from American Psychiatric Association1 and Rogers and Wolfe.10

Anxiety occurs occasionally during the use of CNS depressants, especially in children and the elderly; however, anxiety complaints are more common as complications of drug withdrawal after the abrupt discontinuation of these agents.6–10

### PATHOPHYSIOLOGY

Data from biochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain and abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ-aminobutyric acid (GABA), serotonin (5-HT), corticotrophin-releasing factor (CRF), and cholesystokinin.11 Current neuroanatomical models of fear (i.e., the response to danger) and anxiety (i.e., the feeling of fear that is disproportionate to the actual threat) include some key brain areas. The amygdala, a temporal lobe structure, plays a critical role in the assessment of fear stimuli and learned response to fear.11,12 The locus ceruleus (LC), located in the brain stem, is the primary NE-containing site, with widespread projections to areas responsible for implementing fear responses (e.g., vagus, lateral and paraventricular hypothalamus). The hippocampus is integral in the consolidation of traumatic memory and contextual fear conditioning. The hypothalamus is the principal area for integrating neurotransc and autonomic responses to a threat.11,12

### NEUROCHEMICAL THEORIES

**Noradrenergic Model**

The basic premise of the noradrenergic theory is that the autonomic nervous system of anxious patients is hypersensitive and overreacts to various stimuli. Many anxious patients clearly display symptoms of peripheral autonomic hyperactivity. In response to threat or fearful situations, the LC serves as an alarm center, activating NE release and stimulating the sympathetic and parasympathetic nervous systems. Chronic central noradrenergic overactivity downregulates α2-adrenoreceptors in patients with GAD. This receptor is hypersensitive in some patients with panic disorder.11 By administering drugs that have a relatively specific effect on the LC, researchers have further explored the NE theory of anxiety and panic disorder. Drugs with anxiogenic effects (e.g., yohimbine [an α2-adrenergic receptor antagonist]) stimulate LC firing and increase noradrenergic activity. NE in turn increases glutamate release (an excitatory neurotransmitter).11 This produces subjective feelings of anxiety and can precipitate a panic attack in those with panic disorder, but not in normal volunteers.11 Drugs with anxiolytic or antipanic effects
(e.g., benzodiazepines and antidepressants) inhibit LC firing, decrease noradrenergic activity, and block the effects of anxiogenic drugs.11

**GABA Receptor Model**

There are two superfamilies of GABA protein receptors: GABA<sub>A</sub> and GABA<sub>B</sub>. Drugs that reduce anxiety and produce sedation target the GABA<sub>A</sub> receptor. The GABA<sub>A</sub> receptor is a G-protein-coupled receptor postulated to be involved in the presynaptic inhibition of GABA release.11–13 GABA<sub>A</sub> receptors are ligand-gated ion channels composed of five protein subunits (i.e., α<sub>1</sub>, α<sub>2</sub>, β<sub>1</sub>, γ<sub>1</sub>, δ, ε, θ, π, ρ<sub>1</sub>, ) surround a central pore, and the receptor is connected to the cytoskeleton.14 Benzodiazepine ligands enhance the inhibitory effects of GABA.11,13 GABA, the major inhibitory neurotransmitter in the CNS, has a strong regulatory or inhibitory effect on the 5-HT, NE, and dopamine (DA) systems. When GABA binds to the GABA<sub>A</sub> receptor, neuronal excitability is reduced.

The specific role of the GABA receptors in anxiety disorders has not been established. The number of GABA<sub>A</sub> receptors can change with alterations in the environment (e.g., chronic stress), and the subunit expression can be altered by hormonal changes.14 In patients with GAD, benzodiazepine binding in the left temporal lobe is reduced.14 Abnormal sensitivity to antagonism of the benzodiazepine binding site and decreased binding was demonstrated in panic disorder.11,14 This is consistent with the suggestion that panic disorder is secondary to a lack of central inhibition that results in uncontrolled elevations in anxiety during panic attacks.15 Growth hormone response to baclofen in patients with generalized SAD suggests an abnormality of central GABA<sub>A</sub> receptor function.15

**Serotonin Model**

Although there are data suggesting that the 5-HT system is dysregulated in patients with anxiety disorders, definitive evidence that shows a clear abnormality in 5-HT function is lacking. 5-HT is primarily an inhibitory neurotransmitter that is used by neurons originating in the raphe nuclei of the brain stem and projecting diffusely throughout the brain (e.g., cortex, amygdala, hippocampus, and limbic system). Abnormalities in serotonergic functioning through release and uptake at the presynaptic autoreceptors (5-HT<sub>1A</sub>), the serotonin reuptake transporter (SERT) site, or effect of 5-HT at the postsynaptic receptors (e.g., 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub>, and 5-HT<sub>2C</sub>) may play a role in anxiety disorders.11,13 Preclinical studies suggest that greater 5-HT function facilitates avoidance behavior; however, primate studies show that reducing 5-HT increases aggression.11,13 It is postulated that greater 5-HT activity reduces NE activity in the LC, inhibits defense/escape response via the periaqueductal gray (PAG) region, and reduces hypothalamic release of CRF. The selective serotonin reuptake inhibitors (SSRIs) acutely increase 5-HT levels by blocking the SERT to increase the amount of 5-HT available postsynthetically, and are efficacious in blocking the manifestations of panic and anxiety.11

Low 5-HT activity may lead to a dysregulation of other neurotransmitters. NE and 5-HT systems are closely linked, and interactions between the two are reciprocal and vary. NE may act at presynaptic 5-HT terminals to decrease 5-HT release, and its activity at postsynaptic receptors can cause increased 5-HT release.

Buspirone is a selective 5-HT<sub>1A</sub> partial agonist that is effective for GAD but not for panic disorder. Because the selective 5-HT<sub>1A</sub> partial agonists reduce serotonergic activity, GAD symptoms may reflect excessive 5-HT transmission or overactivity of the stimulatory 5-HT pathways.16 The comparable efficacy of the serotonin-norepinephrine reuptake inhibitor (SNRI), extended-release venlafaxine, at high and low dosages suggests that 5-HT (rather than NE) reuptake blockade contributes to the therapeutic effect in SAD.17
The onset, course of illness, and comorbid conditions of GAD are important considerations. GAD has a gradual onset with an average age of 21 years; however, there is a bimodal distribution. Onset occurs earlier when GAD is the primary presentation and later when GAD is secondary. GAD can be exacerbated or precipitated in later life by severe psychologic stressors. Most patients present between the ages of 35 and 45 years, with women twice as likely to have GAD as men. GAD is the most common anxiety disorder in patients older than 55 years of age. Tension surrounding life events also can play a role in the persistence of symptoms. The course of the illness is chronic (i.e., episodes can last for a decade or longer); there is a high percentage of relapse and low rates of recovery. The likelihood of remission at 2 years is 25%. Patients report substantial interference with their lives and have a high probability of seeking treatment. Lifetime comorbidity with another psychiatric disorder occurs in 90% of patients with GAD, with depression being found in over 60%.

### PANIC DISORDER

Panic disorder begins as a series of unexpected (spontaneous) panic attacks involving an intense, terrifying fear similar to that caused by life-threatening danger. The unexpected panic attacks are followed by at least 1 month of persistent concern about having another panic attack, worry about the possible consequences of the panic attack, or a behavioral change related to the attacks. During an attack, patients describe at least four physiologic and physical symptoms. Panic attacks usually last no more than 20 to 30 minutes, with the peak intensity of symptoms within the first 10 minutes. Often patients seek help at a physician’s office or emergency department, only to have their symptoms resolve before or on arrival. Because panic symptoms mimic those present in several medical conditions, patients often are misdiagnosed, and multiple referrals are common.

### CLINICAL PRESENTATION OF A PANIC ATTACK

#### Psychological Symptoms
- Depersonalization
- Derealization
- Fear of losing control, going crazy, or dying

#### Physical Symptoms
- Abdominal distress
- Chest pain or discomfort
- Chills
- Dizziness or light-headedness
- Feeling of choking
- Hot flashes
- Palpitations
- Nausea
- Paresthesias
- Shortness of breath
- Sweating
- Tachycardia
- Trembling or shaking

Secondary to the panic attacks, up to 70% of patients develop agoraphobia. Agoraphobia is anxiety about being in places or situations in which escape might be difficult or where help might not be available in the event of a panic attack. As a result, patients often avoid specific situations (e.g., being in a crowd or flying) in which they fear a panic attack might occur.

Complications of panic disorder include depression (10%–65% have major depressive disorder), alcohol abuse, and high use of health services and emergency rooms. Patients with panic disorder have a high lifetime risk for suicide attempts compared with the general population.

### SOCIAL ANXIETY DISORDER

SAD is characterized by an intense, irrational, and persistent fear of being negatively evaluated or scrutinized in at least one social or performance situation. Exposure to the feared circumstance usually provokes an immediate situation-related panic attack. Blushing is the principal physical indicator and distinguishes SAD from other anxiety disorders. Adults with SAD usually recognize their fear is excessive and unreasonable; however, they are unable to overcome it without treatment. If necessary, the feared situation is avoided or endured with significant distress. In individuals younger than 18 years of age, the duration of symptoms must be at least 6 months to meet the diagnostic criteria.

#### CLINICAL PRESENTATION OF SOCIAL ANXIETY DISORDER

##### Fears of Being
- Scrutinized by others
- Embarrassed
- Humiliated

##### Some Feared Situations
- Eating or writing in front of others
- Interacting with authority figures
- Speaking in public
- Talking with strangers
- Use of public toilets

##### Physical Symptoms
- Blushing
- “Butterflies in the stomach”
- Diarrhea
- Sweating
- Tachycardia
- Trembling

##### Types
- Generalized: fear and avoidance extend to a wide range of social situations
- Nongeneralized: fear limited to one or two situations

Data from American Psychiatric Association, Muller et al., and Schneier.
the distinction between the two is the rationale behind fear; fear of anxiety symptoms is characteristic of panic disorder, whereas fear of embarrassment from social interaction typifies SAD. A majority of SAD patients eventually develop a concurrent mood, anxiety, or substance abuse disorder.17,23

SPECIFIC PHOBIA

Specific phobia is marked and persistent fear of a circumscribed object or situation (e.g., insects, or heights). Apart from contact with the feared object or situation, the patient is usually free of symptoms. Most persons simply avoid the feared object and adjust to certain restrictions on their activities.1

TREATMENT

Generalized Anxiety Disorder

DESIRABLE OUTCOME

The goals of therapy in the acute management of GAD are to reduce the severity and duration of the anxiety symptoms and to improve overall functioning. The long-term goal in GAD is remission with minimal or no anxiety symptoms, no functional impairment, and increased QOL.2 Prevention of recurrence is another long-term consideration.

GENERAL APPROACH TO TREATMENT

Once GAD is diagnosed, a patient-oriented treatment plan, which usually consists of both psychotherapy and drug therapy, is developed. The plan depends on the severity and chronicity of symptoms, age, medication history, and comorbid medical and psychiatric conditions.8,25 Factors such as anticipated adverse effects, history of prior response in the patient or family member, patient preference, and cost should be considered when treatment is initiated. Psychotherapy is the least invasive and safest treatment modality. Antianxiety medication is indicated for patients experiencing symptoms severe enough to produce functional disability. Table 79–3 lists drug choices for GAD, panic disorder, and SAD.

Data from Bandelow et al.,1 Davidson et al.,2 Baldwin et al.,17 Schneier,24 and American Psychiatric Association.26

Nonpharmacologic treatment modalities in GAD include psychoeducation, short-term counseling, stress management, psychotherapy, meditation, or exercise. Psychoeducation includes information on the etiology and management of GAD. Anxious patients should be instructed to avoid caffeine, nonprescription stimulants, diet pills, and excessive use of alcohol. Most patients with GAD require psychologic therapy, alone or in combination with antianxiety drugs, to overcome fears and to learn to manage their anxiety and worry. Cognitive behavioral therapy (CBT) is the most effective psychologic therapy in GAD patients. CBT for GAD includes self-monitoring of worry, cognitive restructuring, relaxation training, and rehearsal of coping skills. Psychotherapy or medication alone have comparable efficacy in acute treatment.21 The relapse rate with CBT is less than with other types of psychologic modalities.21 Controlled trials comparing the efficacy of combining drug and psychotherapy over long-term treatment are lacking.21 Advantages of CBT over pharmacotherapy include patient preference and lack of troubling adverse effects. However, CBT is not widely available, requires specialized training, and entails weekly sessions for an extended time period (i.e., 12–20 weeks).3

PHARMACOLOGIC THERAPY

The benzodiazepines are the most effective, safe, and commonly prescribed drugs for the rapid relief of acute anxiety symptoms (Table 79–4). All benzodiazepines are equally effective anxiolytics, and consideration of pharmacokinetic properties and the patient’s clinical situation will assist in the selection of the most appropriate agent.

Because of the lack of dependency and tolerable adverse effect profile, antidepressants have emerged as the treatment of choice for the management of chronic anxiety, especially in the presence of comorbid depressive symptoms. Buspirone is an additional anxiolytic option (Table 79–5) in patients without comorbid depression or other anxiety disorders (e.g., panic disorder and SAD). Because of the high risk of adverse effects and toxicity, barbiturates, antipsychotics, antipsychotic-antidepressant combinations, and anti-histamines generally are not indicated in the treatment of GAD.3 The benzodiazepines are more effective in treating the somatic and autonomic symptoms of GAD as opposed to the psychic symptoms (e.g., apprehension and worry), which are reduced by antidepressants.3

4Panic disorder dose.
Equivalent doses from Chouinard.27
The most recent treatment guidelines from the World Federation of Societies of Biological Psychiatry and the British Association of Psychopharmacology are evidence-based. A descriptive flowchart with recommendations based on levels of evidence from the International Psychopharmacology Algorithm Project for the psychosocial and pharmacologic management of GAD is shown in Figure 79–1.

### Alternative Drug Treatments

Hydroxyzine, pregabalin, and atypical antipsychotics are alternatives. The antihistamine hydroxyzine was effective in studies conducted for as long as 12 weeks in patients with GAD. Hydroxyzine is commonly used in the primary care setting, but it is considered be to a second-line agent because of adverse effects and lack of efficacy for comorbid disorders. Pregabalin, which binds to the α₇ subunit of voltage-gated calcium channels to reduce nerve terminal calcium influx, acts on “hyperexcited” neurons. Pregabalin produced anxiolytic effects similar to lorazepam, alprazolam, and venlafaxine in acute efficacy trials. Extended-release quetiapine 150 mg/day monotherapy was superior to placebo in 3 studies, and as effective as paroxetine 20 mg/day and escitalopram 10 mg/day but with an earlier onset of action. In a 52-week treatment of GAD, extended-release quetiapine was superior to placebo in the prevention of anxiety relapse. Quetiapine is not FDA approved for GAD, and the long-term risks and benefits of atypical antipsychotics in the treatment of GAD are unclear. Analysis of data from pooled sample trials found kava-kava to be no more effective than placebo. Because of reports of hepatotoxicity, kava-kava is not recommended as an anxiolytic.

### Special Populations

The management of anxiety in patients with substance abuse, pregnant women, children, elderly patients, and those patients with adherence problems requires special consideration in the choice of anxiolytic. Patients with GAD may misuse alcohol, cannabis, or other substances to manage anxiety. The symptoms of GAD are similar to those of withdrawal, and it is difficult to confirm the diagnosis of GAD until after abstinence is obtained. Benzodiazepine therapy should be avoided in this population.

There is evidence that maternal anxiety during pregnancy and the post-partum period potentially pose significant risk to the child. Clinical practice guidelines for anxiety disorders recommend use of fluoxetine, sertraline, or citalopram; however, perinatal syndromes (e.g., jitteriness, myoclonus, irritability) in the neonate and premature delivery have been reported. Paroxetine (Category D) should be avoided in pregnant women because of risk of cardiovascular malformations.

Cleft lip, cleft palate, and other teratogenic effects are associated with benzodiazepine use, but a causal relationship is inconclusive. Clinicians should avoid benzodiazepine use during the first trimester, use the lowest dosage for the shortest period of time, divide the total daily dosage into two or three doses to prevent high peak plasma levels, and use the agent as monotherapy. Benzodiazepine risks during the third trimester include sedation, withdrawal symptoms, and “floppy” infant syndrome (e.g., hypotonia, low Apgar scores, hypothermia). Alprazolam should be avoided during pregnancy because of neonatal withdrawal. Should benzodiazepines be required during pregnancy, the preferred agents are clonazepam and lorazepam. The antidepressants are favored for GAD during pregnancy based on safety considerations. Diazepam and clonazepam should not be used in nursing mothers because infants can experience sedation, lethargy, and weight loss.

There are few controlled clinical trials of drugs in children and adolescents with GAD. CBT alone or in conjunction with antidepressants can have long-term benefits. Randomized controlled trials of fluvoxamine, fluoxetine, sertraline, and extended-release venlafaxine indicate short-term efficacy, however, behavioral activation was reported with clonazepam. No antidepressant is FDA-indicated for GAD in children or adolescents. Increased monitoring for behavioral activation with benzodiazepines and suicide-related adverse effects with antidepressants is necessary if these agents are prescribed.

Patients with hepatic disease are at risk for drug accumulation and subsequent complications. Duloxetine use should be avoided in patients with hepatic insufficiency. Drug accumulation can result in the elderly secondary to a decreased capacity for oxidation and alterations in the volume of distribution. Therefore, intermediate- or short-acting benzodiazepines without active metabolites are preferred for chronic use. Elderly patients are also sensitive to the CNS adverse effects of benzodiazepines (regardless of half-life), and use is associated with a high frequency of falls and hip fractures. Venlafaxine, citalopram, duloxetine, and pregabalin showed efficacy in elderly patients with GAD.

### Antidepressant Therapy

Antidepressants are considered first-line agents in the management of GAD. Extended-release venlafaxine, duloxetine, paroxetine, and escitalopram are FDA-approved antidepressants for GAD. Imipramine is considered when patients fail to respond to SSRIs or venlafaxine (see Table 79–5). The anxiety response of antidepressants is delayed by 2 to 4 weeks or longer. The pharmacokinetics and drug interactions of the antidepressants are reviewed in the chapter on depressive disorders (Chapter 77).

### Efficacy

Antidepressants are efficacious in the acute and long-term management of GAD. Data support the use of SSRIs...
1. Diagnosis of generalized anxiety disorder (GAD)

2. Evaluate for comorbidity, suicidality, insomnia, substance abuse, non-compliance, childbearing potential, elderly patient, cultural issues.

3. Treatment?
   - Psychosocial
   - Medical

4. PST

5. SSRI/SNRI: 4–6 week evaluation with adequate dosing.

6. Assessment for initial response
   - Adequate trial & good response
   - Inadequate trial

7. Continue treatment for at least one year.
   - 7a. For at least one year.
   - 7b. For at least one year.
   - 7c. For at least one year.

8. Assessment for partial response
   - Full symptom persistence
   - Partial response

9. Hypnotics: non-BZD GABAergic hypnotic drugs, BZD, trazodone, mirtazapine; lifestyle changes; alternatively a sedating AH can be added.

10. Augment with AAP or add an BZD, AH, buspirone or tiagabine (with caution). PST could be added.

11. Switch to another AD (within class or to a different class, SSRI to SNRI or SNRI to SSRI).

12. Assessment for response
   - Improved or remission
   - Partial or non-response

13. Evaluate for significant comorbidity
   - Yes
   - Comorbid depression
   - Comorbid stable bipolar disorder
   - Comorbid other anxiety disorders

14. Adequate dose AD or augmentation with bupropion, buspirone or AAP or chromium picolinate. Severe depression may need ECT.

15. Add mood stabilizer, anticonvulsant or AAP. May need laboratory monitoring.

16. For panic disorder, add TCA, SSRI/SNRI or BZD; for SAD add BZD, SRI, AAP, pregabalin, or LEV; for OCD, add SSRI or CMI; for PTSD, add SSRI, SNRI, AAP or prazosin.

17. Switch to another combination that includes SSRI, SNRI, NaSSa or TCA or add a third drug of different class from other two. PST can also be added.

18. Assessment for response
   - Adequate
   - Partial or non-response

Key: AAP = atypical antipsychotic; AD = antidepressant; AH = antihistamine; BZD = benzodiazepine; CMI = clomipramine; ECT = electroconvulsive therapy; GAD = generalized anxiety disorder; LEV = levetiracetam; NaSSa = noradrenergic and selective serotonin reuptake antidepressant; PST = psychosocial treatment; SAD = social anxiety disorder; SNRI = serotonin and noradrenaline reuptake inhibitor; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant.

FIGURE 79-1. International Psychopharmacology Algorithm Project (IPAP) Generalized Anxiety Disorder (GAD) Algorithm Flowchart. Yellow, first-line treatment (Nodes 3-6); Green, second-line treatment (Nodes 8-12); Blue, third-line treatment, no comorbidity (Nodes 13-19); Orange, third-line treatment, with comorbidity (Nodes 14-16); Light green, assessment and evaluation. Levels of evidence used in development of the flowchart were: 1 = more than one placebo-controlled trial with sample sizes over 30; 2 = one placebo-controlled trial (or active versus active drug comparison) with sample size of 30 or greater; 3 = one or small (n < 30) placebo-controlled trial; 4 = case reports or open-label trials; and 5 = expert consensus without published evidence. (Flowchart is used by permission of the International Psychopharmacology Algorithm Project, http://www.ipap.org)
(e.g., escitalopram, paroxetine, sertraline) and SNRIs (e.g., extended-release venlafaxine and duloxetine) for acute therapy (8–12 week trials), with response rates between 60% to 68%, and remission rates of 30%,21 Data show that duloxetine 60 mg and 120 mg daily produce similar remission rates as other antidepressants.39 In a comparative trial, there was no difference in efficacy between paroxetine and sertraline.40 Escitalopram 10 mg was superior to paroxetine 20 mg in a fixed-dose study.41 In a comparative trial, extended-release venlafaxine and escitalopram were both effective for GAD, but escitalopram was better tolerated.42

Studies with continued treatment after acute response to SSRIs showed further improvement with escitalopram or paroxetine over 6 months (escitalopram group had fewer withdrawals).43 Continued venlafaxine therapy was associated with a 62.5% rate of remission.44 Relapse-prevention studies found that patients continued on paroxetine or escitalopram achieved remission rates of 73% and 65%, respectively.45 In a four parallel-group comparison, diazepam and trazodone were found to be equivalent in anxiolytic activity (remission rates of 66% and 69%, respectively) compared with placebo (47% remission rate), but imipramine’s rate of remission (73%) exceeded that of the other three treatments.46

Mechanism of Action The mechanism of action of antidepressants in anxiety disorders is not fully understood. Research indicates that antidepressants modulate receptor activation of neuronal signal transduction pathways connected to the neurotransmitters 5-HT, DA, and NE. It is theorized that by activating stress-adapting pathways, SSRIs and SNRIs reduce the somatic anxiety symptoms and the general distress experienced by patients.

Adverse Effects Paroxetine was associated with a high rate of somnolence, nausea, abnormal ejaculation, dry mouth, decreased libido, and anemia compared with placebo.47 Escitalopram caused nausea, insomnia, fatigue, decreased libido, ejaculation disorders, and decreased libido in patients with GAD.48 The most common adverse events of venlafaxine in patients with GAD were nausea, somnolence, and dry mouth.33 The use of TCAs can be limited by troublesome adverse events (e.g., sedation, anticholinergic effects, and weight gain) in some patients and the risk of toxicity in overdose.5 However, in a meta-analysis of antidepressant trials there was no difference in dropout rates between antidepressants (e.g., paroxetine, venlafaxine, and imipramine) compared with placebo, suggesting equivalent tolerability between antidepressants.37

Dosing and Administration The antidepressants can be dosed once a day (see Table 79–5). Some patients require small initial daily doses for the first week of therapy. Paroxetine doses greater than 20 mg/day have not been found to be more effective.30

Benzodiazepine Therapy

Although all benzodiazepines possess anxiolytic properties, only 7 of the 13 currently marketed agents have FDA approval for the treatment of GAD (see Table 79–4). Estazolam, flurazepam, temazepam, quazepam, and triazolam are marketed as sedative-hypnotic agents. Clonazepam is marketed as an antipsychotic agent and anticonvulsant,48 and midazolam is labeled for preoperative sedation. Alprazolam is indicated for the treatment of panic disorder with or without agoraphobia, as well as GAD.49

Pharmacology and Mechanism of Action The GABA receptor model of anxiety theorizes that benzodiazepines ameliorate anxiety through potentiation of the inhibitory activity of GABA.14 Benzodiazepines bind on the GABA receptor at the α, β, and γ subunits in combination with a β subunit and the γ subunit.14 The anxiolytic effects of benzodiazepines are mediated at the α site while sedative effects result from binding at the γ subunit. The binding sites of benzodiazepines and GABA are at the receptor interfaces of α/β and α/γ, respectively. The GABA receptor controls tonic inhibition to reduce neuronal excitability.14 Other neurotransmitters (e.g., 5-HT, NE, and DA) may also be involved in benzodiazepine activity.

Pharmacokinetics A wide difference in milligram potency exists between the benzodiazepine compounds; however, when appropriately dosed, all agents have similar anxiolytic and sedative-hypnotic activity. The variations in lipid solubility between compounds influence the pharmacokinetic properties of benzodiazepines. Knowledge of the different pharmacokinetic and pharmacodynamic properties can assist in choosing an appropriate anxiolytic (Table 79–6). After a single dose, the onset, intensity, and duration of pharmacologic effects are important factors to consider when using benzodiazepines for the short-term, intermittent, or as-needed treatment of anxiety.

The primary determinant of a drug’s onset of effect after a single oral dose is the rate of drug absorption. Because of high lipophilicity, diazepam and clorazepate are absorbed rapidly and distributed quickly into the CNS. Therefore the onset of anxiolytic effect occurs within 30 to 60 minutes, which results in a rapid and intense relief of anxiety. High lipophilicity also increases the extent of drug redistribution into the periphery, particularly adipose tissue, resulting in a shorter duration of effect after a single dose than suggested by single-dose elimination.

Data from Rissenbaum et al and Facts and Comparisons.46

*Desmethyldiazepam (DMDZ) half-life 50–100 h.*
half-life studies. Clinically, patients perceive a rapid onset of action, but some experience an unpleasant feeling of drowsiness or loss of control. This “rush” can be euphoric and contribute to abuse.

Compared with diazepam, lorazepam and oxazepam are relatively less lipophilic and have a slower absorption and onset of effect. These benzodiazepines have smaller volumes of distribution and a resulting longer duration of action.

Parenteral administration via the intramuscular route should be avoided with diazepam and chlordiazepoxide secondary to variability in the rate and extent of drug absorption. Intramuscular lorazepam provides rapid, reliable, and complete absorption.

After multiple dosing, the rate and extent of drug accumulation are functions of the drug’s elimination half-life in relation to dosing intervals, clearance, and formation of active metabolites. Differences in clinical effects that occur during and after repeated dosages with the benzodiazepines are related in part to variability in metabolism and metabolite accumulation.

The benzodiazepines undergo two primary metabolic processes, hepatic oxidation (catalyzed by cytochrome P450 3A4) and glucuronide conjugation. With the exception of lorazepam and oxazepam (which are conjugated only) and clonazepam (which undergoes nitroreduction), all benzodiazepines are oxidized first and then conjugated and excreted readily. Diazepam’s metabolism is also catalyzed by cytochrome P450 2C19. Oxidation can be impaired in patients with liver disease, in the elderly, and in those who simultaneously use drugs that inhibit oxidation resulting in higher levels of the parent drug and/or an active metabolite.

Many benzodiazepines are converted to desmethyldiazepam (DMDZ), an active metabolite with a long elimination half-life (Table 79–6). DMDZ is further oxidized to oxazepam and then conjugated and excreted. After multiple dosing, accumulation of DMDZ is slow and extensive, providing a long-lasting anxiolytic effect. If oxidation of DMDZ is impaired, the half-life is prolonged, and extensive drug accumulation can result with repeated dosing.

Clorazepate is a prodrug and possesses no anxiolytic effects until metabolized to DMDZ. Before absorption, clorazepate is metabolized rapidly in the stomach through a pH-dependent process under acidic conditions.

Benzodiazepines with shorter half-lives (e.g., alprazolam, lorazepam, and oxazepam) reach steady-state plasma concentrations rapidly, and drug accumulation after repeated dosing is minimal. Oxazepam and lorazepam have no active metabolites.

Benzodiazepine protein binding is extensive, especially for the drugs with a long elimination half-life. After a single dose of a benzodiazepine with a long elimination half-life, the expected duration of clinical activity may not parallel the drug’s pharmacokinetic half-life because of drug redistribution. After multiple dosing, drugs with long elimination half-lives and active metabolites require 1 to 2 weeks to reach steady state.

Efficacy Clinical trials of benzodiazepines show that 65% to 75% of patients with GAD have a marked to moderate response, with most of the improvement occurring in the first 2 weeks of therapy. Benzodiazepines are more effective on the somatic symptoms of anxiety and fail to obviate the cognitive or psychic symptoms (e.g., worry). Up to 50% of patients fail to reach remission with benzodiazepine therapy, and rates of relapse exceed that of the antidepressants.

Adverse Effects The most common adverse events associated with benzodiazepine therapy involve CNS depression. This is manifested clinically as drowsiness, sedation, psychomotor impairment, and ataxia. A transient mild drowsiness is experienced commonly by patients during the first few days of treatment; however, tolerance often develops. Disorientation, depression, confusion, irritability, aggression, and excitement are reported.

Impairment of memory and recall also can occur during benzodiazepine treatment. The memory loss induced by the benzodiazepines typically is limited to events occurring after drug ingestion (anterograde amnesia). Anterograde amnesia is secondary to disordered consolidation processes that store information and is not impairment in the perception or retrieval of information. Benzodiazepines with high affinity for binding to the benzodiazepine receptor (e.g., alprazolam) appear to possess a higher potential for amnesia.

Abuse, Dependence, Withdrawal, and Tolerance Two serious complications of benzodiazepine therapy are the potential for abuse and development of physical dependence. Benzodiazepine abuse is rare in the general population of users; however, individuals with a history of multiple drug abuse (e.g., alcohol or sedatives) are at the greatest risk for becoming benzodiazepine abusers.

Because of the chronicity of illness, persons with GAD and panic disorder are at high risk of developing benzodiazepine dependence. Benzodiazepine dependence is a physiologic phenomenon demonstrated by the appearance of a predictable abstinence syndrome (withdrawal symptoms) on abrupt discontinuation of therapy. Withdrawal symptoms can result because of the sudden dissociation of a benzodiazepine from its receptor site. After abrupt discontinuation, an acute decrease in GABA neurotransmission results, producing a less inhibited CNS.

Benzodiazepine Discontinuation After benzodiazepine therapy is discontinued suddenly, several events can occur. Rebound anxiety represents an immediate but transient return of original symptoms having an increased intensity compared with baseline. Recurrence or relapse is the return of original symptoms with similar intensity as before treatment.

Withdrawal symptoms are the emergence of new symptoms and a worsening of preexisting symptoms after benzodiazepine discontinuation. Symptoms can persist for days to weeks and resolve gradually over months.

Common symptoms of benzodiazepine withdrawal include anxiety, insomnia, restlessness, muscle tension, and irritability. Less frequently occurring symptoms are nausea, malaise, coryza, blurred vision, diaphoresis, nightmares, depression, hyperreflexia, and ataxia. Tinnitus, confusion, paranoid delusions, hallucinations, and seizures occur rarely. Seizures can occur with both therapeutic and high doses of benzodiazepines with a short elimination half-life, usually within 3 days of drug discontinuation. They can occur approximately 1 week after discontinuation of agents with a long elimination half-life. High benzodiazepine doses, a long duration of therapy, and concurrent ingestion of drugs that lower the seizure threshold are risk factors for withdrawal seizures.

The onset of withdrawal symptoms in patients ingesting benzodiazepines with short elimination half-lives occurs much earlier (within 24–48 hours) than in those taking benzodiazepines with long elimination half-lives (within 3–8 days). Other factors associated with an increased incidence and severity of benzodiazepine withdrawal include high doses and long-term benzodiazepine therapy.

A strategy to minimize the severity of benzodiazepine withdrawal is a 25% per week reduction in dosage until 50% of the dose is reached, and then dosage reduction by one-eighth every 4 to 7 days. If therapy exceeds 8 weeks, a slow dosage taper over 2 to 3 weeks is recommended; however, if the duration of treatment is 6 months, a taper over 4 to 8 weeks should ensue. Long-term use of benzodiazepines (i.e., 1 year or longer) requires a 2- to 4-month slow taper. Tapering will not eliminate the emergence of withdrawal symptoms entirely but will prevent severe withdrawal. Slow drug taper is extremely important for the drugs with a short elimination half-life, because some individuals have greater difficulty with discontinuation.
Withdrawal symptoms with short half-life benzodiazepines were no more severe than with longer half-life agents, therefore switching from a short- to long-acting benzodiazepine before gradual taper is not supported.\textsuperscript{30,31} Adjunctive use of carbamazepine can help reduce withdrawal severity during the benzodiazepine taper.\textsuperscript{30,31} Patients should avoid the intake of alcohol and stimulants during the withdrawal process. Although tolerance develops to the sedative, muscle relaxant, and anticonvulsant activities, the benzodiazepines do not appear to lose anxiolytic or antipanic efficacy. The anxiolytic efficacy of benzodiazepines in long-term clinical trials (greater than 6–8 months of chronic use) has not been reported.\textsuperscript{3}

**Drug Interactions** Drug interactions with the benzodiazepines generally fall into two categories: pharmacodynamic and pharmacokinetic. Simultaneous use of alcohol and a benzodiazepine results in additive CNS depressant effects. In addition, concurrent use of a benzodiazepine and other drugs with CNS depressant properties (e.g., opioids, antipsychotics, and antihistamines) can potentiate the adverse sedative effects. When ingested alone in an overdose attempt, benzodiazepines are rarely life-threatening; however, the combination of benzodiazepines with alcohol or other CNS depressant agents is potentially fatal.

Concurrent use of medications that inhibit cytochrome P450 3A4 (e.g., ketoconazole, nefazodone, and ritonavir) can increase the blood levels of alprazolam and diazepam. Drugs that induce cytochrome P450 3A4 (e.g., carbamazepine, St. John’s wort) can reduce benzodiazepine levels. Consult a drug interaction Website (e.g., http://online.factsandcomparisons.com) for further information.

**Dosing and Administration** Benzodiazepine dosage requirements vary widely among patients and must be individualized. Therapy should be initiated using low doses (e.g., alprazolam 0.25 mg 3 times a day or equivalent doses of other benzodiazepines) and titrated upward to relieve anxiety symptoms and avoid adverse events. After an initial treatment response is achieved, agents with long elimination half-lives can be dosed at bedtime. Dosage adjustments should be made weekly. Three to four weeks of a daily dose at the maximum dose constitutes an adequate clinical trial (see Table 79–4).\textsuperscript{2}

The duration of benzodiazepine therapy for the acute management of anxiety should be limited to 2 to 4 weeks. In general, benzodiazepines should be used with a regular dosing regimen and not on an as-needed basis.\textsuperscript{9} Only in the treatment of short-term distress (e.g., air travel, dental phobia) as-needed use may be justified.\textsuperscript{38} Individuals with persistent symptoms should be managed with antidepressants because of the risk of dependence with continued benzodiazepine therapy.\textsuperscript{25}

Patient education should include the anticipated length of drug therapy, potential side effects, and consequences of the ingestion of alcohol and other CNS depressants. Patients should understand that benzodiazepines provide symptomatic relief but do not solve underlying psychologic problems. Patients should be instructed not to decrease or discontinue benzodiazepine usage without contacting their prescriber.

**Buspirone Therapy**

Buspirone is a nonbenzodiazepine anxiolytic that lacks anticonvulsant, muscle relaxant, hypnotic, motor impairment, and dependence properties. It is considered to be a second-line agent for GAD because of inconsistent reports of efficacy (particularly long term), delayed onset of effect (i.e., 2 weeks or longer), and lack of efficacy for other potential concurrent depressive and anxiety disorders.\textsuperscript{21,32} Unlike benzodiazepines, buspirone is effective for the psychic symptoms of anxiety.\textsuperscript{32}

**Pharmacology and Mechanism of Action** Buspirone’s anxiolytic mechanism of action is unknown. It is thought to exert its anxiolytic effect through partial agonist activity at the 5-HT\textsubscript{1A} presynaptic receptors, thus reducing the firing of 5-HT neurons.\textsuperscript{52}

**Pharmacokinetics** After an oral dose, buspirone is absorbed rapidly and completely and undergoes extensive first-pass metabolism. The mean elimination half-life is 2.5 hours, and it must be dosed 2 to 3 times daily, which adversely affects adherence to the drug regimen.\textsuperscript{23}

**Adverse Effects** Adverse events include dizziness, nausea, and headaches.\textsuperscript{25}

**Drug Interactions** Drugs that inhibit cytochrome P450 3A4 (e.g., verapamil, itraconazole, fluvoxamine) can increase buspirone levels. Rifampin caused a 10-fold reduction in buspirone levels. Buspirone reportedly elevates blood pressure in patients taking a monoamine oxidase inhibitor (MAOI).

**Dosing and Administration** The dose of buspirone can be titrated in increments of 5 mg/day every 2 to 3 days as needed.\textsuperscript{28} The onset of improvement in psychic symptoms precedes the relief of somatic symptoms; maximum therapeutic benefit might not be evident for 4 to 6 weeks.

Buspirone is a treatment option for patients with GAD, particularly for patients with uncomplicated GAD, in patients who fail other anxiolytic therapies, or in patients with substance abuse. It is not useful in clinical situations requiring immediate anxiolysis or for patients requiring as-needed anxiolytic therapy.\textsuperscript{22} The use of benzodiazepines within the month previous to initiation of buspirone therapy was associated with reduced efficacy of buspirone because of its delayed onset in the reduction of somatic symptoms.\textsuperscript{25}

### PHARMACOECONOMIC CONSIDERATIONS

The total annual cost of anxiety disorders has been estimated to be between $42.3 billion and $46.6 billion, of which more than 75% can be attributed to morbidity, mortality, lost productivity, and other indirect costs.\textsuperscript{33} The total cost estimate for anxiety disorders comprises more than 30% of the total expenditures for mental illnesses; the cost of anxiety drug therapy accounts for 53% of the drug expenditures for mental illnesses.\textsuperscript{33} GAD is associated with high rates of healthcare use and disability. The number of days missed from work increases when GAD is concurrent with one or more other psychiatric disorders. Patients with GAD tend to use family practitioners and gastroenterologists more frequently than healthy controls.\textsuperscript{34} GAD ranks third among anxiety disorders in the rate of use of primary care physician time, and it is the leading cause of disability in the workplace in the United States.\textsuperscript{34} Two decision analyses for GAD were published by researchers in the United Kingdom: venlafaxine was more cost-effective than diazepam,\textsuperscript{35} and escitalopram was associated with higher treatment success and lower discontinuation rates and costs than paroxetine.\textsuperscript{36}

**CLINICAL CONTROVERSY**

It is unclear if combining pharmacotherapy with CBT in patients with GAD confers greater overall efficacy than treatment with either approach alone. CBT is an option if patients fail consecutive antidepressant trials, however many patients lack access to CBT.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Initially, anxious patients should be monitored once every 2 weeks\textsuperscript{21} for a reduction in the frequency, duration, and severity of
anxiety symptoms and improvement in functioning. The clinician should assess the patient for response to treatment by asking about specific target symptoms of anxiety and emergence of adverse events. Ideally, the patient should have no or minimal anxiety or depressive symptoms and no functional impairment. Use of an objective measurement of remission of GAD (e.g., Hamilton Rating Scale for Anxiety score less than or equal to 7 and a Sheehan Disability Scale score less than or equal to 1 on each item) can assist in the evaluation of drug response. The definition of treatment resistance is defined as a poor, partial, or lack of response with at least two antidepressants from different classes. Treatment strategies for patients who do not achieve an appropriate response with a first-line agent include increasing the dose of the SSRI/SNRI; changing to a different agent in the same class; changing to a different agent of a different class; or augmentation of therapy. At any point of nonresponse or loss of previous response, the clinician should assess for symptoms that may suggest a need for additional new medications, cause treatment nonadherence, or change management (e.g., suicidal thoughts, psychotic symptoms, substance abuse). Once a patient has responded to pharmacotherapy, the regimen should be continued for at least 1 year. Early discontinuation is associated with a greater risk of relapse.

TREATMENT

Panic Disorder

DESIRED OUTCOME

The goal of therapy in panic disorder is remission. Patients should be free of panic attacks, have no or minimal anticipatory anxiety and agoraphobic avoidance, and no functional impairment. Naturalistic studies indicate that after pharmacotherapy, over 50% of patients have occasional panic attacks, 40% experience agoraphobic avoidance, and most continue to take medications.

GENERAL APPROACH TO TREATMENT

Therapeutic options include single or combined pharmacologic agents, concurrent psychotherapy, or psychotherapy followed by pharmacotherapy. Most patients without agoraphobic avoidance will improve with pharmacotherapy alone; however, if avoidance is present, CBT is typically initiated concurrently. With all effective drug therapies, resolution of agoraphobic avoidance tends to occur slowly. A meta-analysis of 11 randomized clinical trials comparing the use of SSRIs, TCAs, and CBT showed the effect on global anxiety and response to be similar among all treatments.

In the most comprehensive study to date, efficacy of imipramine alone and CBT alone were equivalent in acute therapy for 3 months and during 6 months of maintenance therapy. Combined imipramine and CBT therapy was not significantly better than CBT or imipramine alone for acute therapy but was significantly better during maintenance. At 6 months after discontinuation, only patients previously treated with CBT maintained improvement (4% relapse) compared with a 25% relapse rate in patients previously treated with imipramine. Adding psychosocial treatment to pharmacotherapy may improve long-term outcomes by reducing the likelihood of relapse when pharmacotherapy is stopped.

NONPHARMACOLOGIC THERAPY

Patients should be educated to avoid substances that can precipitate panic attacks, including caffeine, nicotine, alcohol, drugs of abuse, and nonprescription stimulants. Epidemiologic data suggest that daily smoking increases risk for panic attacks and may be a causal or exacerbating factor in some individuals with panic disorder. Preliminary evidence suggests that aerobic exercise (e.g., walking for 60 minutes or running for 20–30 minutes 4 days/week) may benefit patients with panic disorder. CBT is associated with short-term improvement in 80% to 90% of patients and 6-month improvement in 75% of patients. A course of CBT for panic disorder is 16 to 20 hours in length conducted over a period of 4 months. Bibliotherapy (the use of self-help books), exercise, and Internet-based CBT are other options.

PHARMACOLOGIC THERAPY

Panic disorder is treated effectively with several drugs including SSRIs, the TCA imipramine, and the benzodiazepines alprazolam and clonazepam (Table 79–7). Alprazolam, clonazepam, sertraline, paroxetine, and venlafaxine are approved for this indication. SSRIs are the first-line agents because of their tolerability and efficacy in acute and long-term studies; however, the benzodiazepines are the most commonly used drugs for panic disorder. In a meta-analysis of the pharmacotherapy of panic disorder, the effect size of SSRIs and TCAs did not differ; however, the number of drop-outs in the TCA group (31%) was significantly higher than in the SSRI group (18%). A second meta-analysis comparing efficacy of benzodiazepines, TCAs, and SSRIs in panic disorder concluded that all treatments were equally efficacious with 50% to 80% of patients responding to treatment; however benzodiazepines were less effective for depression. A long-term comparison study of SSRIs (e.g., citalopram, fluoxetine, fluvoxamine, paroxetine) found an equal overall response rate after 4 weeks of treatment. However, acute and long-term adverse effects differed between the drugs. Five practice guidelines have been published. An algorithm for the pharmacologic therapy of panic disorder appears in Figure 79–2.

CHAPTER 79
Anxiety Disorders I: Generalized Anxiety, Panic, and Social Anxiety Disorders
Psychiatric Disorders

FIGURE 79-2. Algorithm for the pharmacotherapy of panic disorder. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized controlled trials [RCT] or at least one RCT); B = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); C = directly based on category III evidence (i.e., nonexperimental descriptive studies); D = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respected authorities). (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) (Data from APA 26 and NICE 63)

The efficacy of antidepressants was demonstrated in acute and long-term trials. Three 12-week, acute trials compared antidepressants. Escitalopram, but not citalopram, reduced the frequency of panic attacks although both improved QOL and reduced disease severity.64 There was no difference in outcomes between paroxetine 40 to 60 mg and sertraline 50 to 150 mg daily.65 Extended-release venlafaxine (75 mg or 150 mg) and paroxetine 40 mg achieved a 44% remission rate compared with that of placebo (24%).66 Double-blind trials indicated that continuing sertraline, citalopram, or imipramine from 3 months to 1 year improved response rates.22 Relapse prevention trials with fluoxetine, imipramine, paroxetine, sertraline, and extended-release venlafaxine resulted in reduced relapse rates compared with placebo.21,26

Benzodiazepines are considered second-line agents. Because of the risk of dependency, benzodiazepines should be used only after several trials of antidepressants have failed.1,21,26 Because of potential emergence of depressive symptoms during treatment, benzodiazepines should not be used as monotherapy in a patient who is clinically depressed or has a history of depression. In patients whose illness is complicated by a history of alcohol or drug abuse, benzodiazepine use should be avoided.26 Controlled trials have established that the short-term (4–6 weeks) addition of alprazolam or clonazepam to antidepressants produces a more rapid therapeutic response, with discontinuation of the benzodiazepine by week 7 of therapy.63

Alternative Drug Treatments

Buspirone, trazodone, bupropion, antipsychotics, antihistamines, and β-blockers are ineffective in panic disorder.3,21,26 The majority of studies assessing the efficacy of MAOIs in treating panic disorder were open labeled and lacked adequate sample sizes. MAOIs are reserved for the most refractory or difficult patients.23

Special Populations

Elderly patients with panic disorder have fewer, less intense symptoms and avoidant behavior than younger patients.67 Youth often present with fear that they are dying or being smothered, and agoraphobia can be manifested as a fear of leaving home.68 CBT is effective in both populations. If pharmacotherapy is used, antidepressants, especially SSRIs, are preferred for management of panic disorder, and benzodiazepines are second-line agents because of potential problems with disinhibition in these two populations.

Antidepressant Therapy

Tricyclic Antidepressants

Efficacy Imipramine is the most studied TCA, alleviating panic attacks in 75% of patients with panic disorder. Imipramine effectively blocks panic attacks within at least 4 weeks; however, maximal improvement (including anphobic response) does not occur until 8 to 12 weeks.26

Adverse Effects Up to 40% of patients experience stimulant-like side effects, including anxiety, insomnia, and jitteriness.26 These side effects often affect patient compliance, prevent medication dosage increases, and interfere with the overall treatment outcome. Other problems with TCA use in panic disorder are well documented and include anticholinergic effects, orthostatic hypotension, delayed onset of antipanic effects, and toxicity in overdose.26 Approximately 25% of patients reportedly discontinue treatment because of side effects, especially weight gain.26

Dosing and Administration When using imipramine, treatment should be slowly increased by 10 mg every 2 to 4 days as tolerated.69

Selective Serotonin Reuptake Inhibitors

Efficacy Clinical studies indicate that all SSRIs are effective in panic disorder.21,26,27,36 The percentage of patients who become panic-free ranges between 60% and 80%.26 The antipanic effect of SSRIs is delayed for at least 4 weeks, and some patients do not respond for 8 to 12 weeks.26

Adverse Effects Typical antidepressant doses of SSRIs can cause side effects of insomnia, jitteriness, restlessness, and agitation, and lead to drug discontinuation in patients with panic disorder. Transient gastrointestinal disturbances occur more frequently with SSRIs than with TCAs. Thus low initial SSRI doses should be
prescribed. Sleep disturbances, headaches, weight gain, and sexual dysfunction often are problematic. Dosing and Administration

Low initial doses of SSRIs are recommended (see Table 79–7) to avoid stimulatory side effects (e.g., insomnia or nervousness), and should be maintained for the first week of therapy. Doses at the upper end of the dosing range can be necessary to achieve response.

Serotonin Norepinephrine Reuptake Inhibitors

Efficacy Approximately 54% to 60% of patients were panic-free on extended-release venlafaxine 75 mg or 150 mg daily. The remission rates were 44% for both dosages in acute efficacy studies.

Adverse Effects The most common adverse effects of extended-release venlafaxine in panic trials were nausea, somnolence, tremors, sweating, and abnormal sexual functioning.

Dosing and Administration The dosage of venlafaxine can be increased at weekly intervals. A dose-response relationship was not evident in clinical trials.

Benzodiazepines

Efficacy The high-potency benzodiazepines clonazepam and alprazolam are the preferred agents. Diazepam and lorazepam are possibly effective in treating panic disorder when taken in sufficient high doses. Alprazolam is an ideal agent for patients who need rapid relief. Therapeutic response to benzodiazepines occurs in 1 to 2 weeks. Relapse rates of 50% or higher are common despite slow drug tapering.

Adverse Effects Patient acceptance of benzodiazepines usually is not a problem, and except for sedation, side effects are reported rarely.

Dosing and Administration Doses of clonazepam can be increased by 0.25 or 0.5 mg every 3 days to 4 mg/day if needed. Alprazolam can be slowly increased over several weeks to reach an ideal dose. The duration of action of immediate-release alprazolam can be as little as 4 to 6 hours with resulting breakthrough symptoms; use of the extended-release alprazolam or clonazepam will avoid this problem. Most patients require 3 to 6 mg/day of alprazolam, and some need higher doses to obtain a full therapeutic (antipanic and antiphobic) response.

Treatment Resistance Common reasons for treatment failures are comorbid psychiatric disorders, rapid dosage increases with resulting intolerable side effects, and underdosage. All standard treatments should be tried before using augmentation strategies. In patients with a partial response to one agent, a low dose of another antipanic agent (e.g., a TCA, benzodiazepine, or an SSRI) can be added.

Phases of Therapy

Acute Phase The main goal of therapy in the acute phase is reduction of symptoms (e.g., resolution of panic attacks, reduction in anxiety and phobic fears, resumption of the patient’s usual activities). The duration of this phase is generally 1 to 3 months depending on the choice of drug. Therapy should be altered if there is no response after 6 to 8 weeks of an adequate dose.

The guiding principle for SSRI and SNRI drugs in panic disorder is to start with low doses (approximately one-quarter to one-half of the starting doses for depression), use an adequate dose, and treat for about 12 weeks. Side effects with the antidepressants, often from too high an initial dose, can prevent achievement of an optimal dosage, compromise treatment response, and contribute to patient nonadherence.

The duration of the acute phase with benzodiazepines is approximately 1 month because response is rapid. A regular dosing schedule rather than an as-needed schedule is preferred for patients with panic disorder who are taking benzodiazepines, where the goal is to prevent panic attacks rather than reduce symptoms once an attack has already occurred.

Maintenance Phase and Discontinuation The optimal length of therapy is unknown; however, the total duration of therapy appears to be 12 to 24 months before drug discontinuation over 4 to 6 months is attempted. The dose used in the acute phase is continued into the maintenance phase. Citalopram, clomipramine, fluoxetine, sertraline, venlafaxine, and imipramine have been shown to maintain clinical effects for up to 1 year of treatment. When drugs are discontinued too early, a high rate of relapse occurs; thus longer periods of treatment are associated with a more sustained response. Reinstitution of drug usually results in renewed clinical response. Pharmacotherapy, even at long duration, might not prevent relapse, and many patients require long-term therapy.

The most important determinant of adherence with maintenance therapy is the tolerability of adverse events. Some adverse events which are experienced short term become unbearable during long-term management (e.g., sexual dysfunction and weight gain). TCAs, SSRIs (except fluoxetine), and venlafaxine can be associated with discontinuation symptoms.

The primary risk of long-term benzodiazepine use is the development of dependency and withdrawal reactions on discontinuation. Abuse of benzodiazepines usually is confined to patients with a personal or family history of substance or alcohol use. The approach to benzodiazepine discontinuation involves a slow and gradual tapering of the dose because withdrawal symptoms and rebound anxiety may occur during discontinuation. Benzodiazepines should be tapered over 2 to 4 months at rates no higher than 10% of the dose per week.

Providing education about the disorder may relieve some of the symptoms of panic by helping the patient to realize that the symptoms are neither life-threatening nor uncommon. Patients should be informed regarding the lag time before a therapeutic response will occur and any problematic side effects. Many patients are reluctant to take drugs for fear that their illness will worsen or that they will become addicted. Adverse events are often perceived as a worsening of the illness and can contribute to nonadherence or prevent necessary dosage increases. Patients receiving benzodiazepines and antidepressants should be told not to decrease or discontinue therapy unless authorized by their clinician.

PHARMACOECONOMIC CONSIDERATIONS

Patients with panic disorder have high rates of unemployment and receive welfare, disability benefits, and healthcare services. They also have impaired emotional and physical health status and experience poor marital and social functioning. Measures of QOL improved with imipramine, clonazepam, sertraline, and venlafaxine. Treatment with clomipramine, paroxetine, or fluoxetine improved work, social, and family responsibilities. Improvements in anxiety and phobic avoidance were significantly associated with QOL improvements. In a cost-efficacy evaluation of individual and combined treatments for panic disorder, imipramine was the most cost-efficacious treatment option at the completion of the acute phase. CBT was the most cost-efficacious option at the end of maintenance treatment and 6 months after treatment termination.

CLINICAL CONTROVERSY

The cognitive effects of benzodiazepines are a subject of debate. Benzodiazepines at higher doses can cause memory impairment. One meta-analysis reported that long-term benzodiazepine users performed worse than controls on domains of cognitive functioning. However, another review concluded that the literature does not provide evidence of long-term cognitive effects of benzodiazepines in patients with anxiety.
EVALUATION OF THERAPEUTIC OUTCOMES

During the first few weeks of the acute phase of therapy, patients with panic disorder should be seen every 1 to 2 weeks when starting a new medication, then every 2 to 4 weeks to adjust drug dosages based on improvement in panic symptoms and to monitor for adverse events. After the dose is stabilized and symptoms have decreased, visits every 2 months should suffice. The patient should be counseled to maintain a diary to record the date, time, frequency, duration, and intensity of panic episodes, level of anticipatory anxiety or agoraphobic avoidance, and the severity of distress and impairment related to panic disorder. Treatment outcomes can be assessed objectively by use of the Panic Disorder Severity Scale. Remission is defined as equal to or less than 3 with no or mild agoraphobic avoidance, anxiety, disability, or depressive symptoms. Treatment response is indicated by a 40% or greater reduction in overall score. At scheduled visits, the clinician can inquire about the level of disability experienced by the patient and have the patient complete the Sheehan Disability Scale (with a goal of less than or equal to 1 point on each item). During drug discontinuation, the frequency of appointments should be increased to evaluate for emergence of potential withdrawal symptoms and monitor for relapse.

TREATMENT

Social Anxiety Disorder

DESIRED OUTCOME

The goals of therapy in the acute phase of treatment are to reduce physiologic symptoms of anxiety (e.g., tachycardia, flushing, and sweating), social anxiety, and phobic avoidance. The duration of this phase is 4 to 12 weeks, depending on the drug therapy.

The goals of therapy in the continuation phase (3–6 months) are to extend the therapeutic benefits, especially the patient’s ability to participate in social activities, and improve QOL. Although the primary goal of treatment is to reduce anxiety symptoms to manageable levels, even modest reductions in avoidance and discomfort can be highly valued by patients.

At least a 1-year maintenance period is recommended to maintain improvement and decrease the rate of relapse. Situations suggesting a possible need for long-term treatment include the presence of unresolved symptoms or comorbidity, an early onset of disease, and a prior history of relapse. The long-term goal in the treatment of SAD is remission with the disappearance of the core symptoms of social anxiety, little or no anxiety, and no functional impairment or concurrent depressive symptoms.

GENERAL APPROACH TO TREATMENT

Patients with generalized SAD should be treated aggressively. Obstacles to effective treatment include patient avoidance of therapy secondary to fear and shame, treatment directed toward somatic symptoms or concurrent conditions, and financial barriers. Patients with SAD often respond more slowly and less completely than patients with other anxiety disorders. Therefore, it is important to set reasonable expectations for response to therapy. Consideration of current symptoms, prior treatments, concurrent conditions, and history of substance abuse guide treatment selection.

CBT and pharmacotherapy are effective in the treatment of SAD. Pharmacotherapy is often the most practical choice because CBT might not be available outside of large urban areas. Acute treatment outcomes for CBT and pharmacotherapy are equal. Drug therapy is superior in reducing subjective general anxiety acutely, although CBT has a greater likelihood of maintaining response after termination. There are no data to predict which patients will respond best to pharmacotherapy, CBT, or a combination or maintain gains after discontinuing pharmacotherapy. The only significant indication of treatment response in pharmacotherapy is duration of treatment. Some patients elect lifelong therapy, and many are reluctant to attempt drug discontinuation because of fear of relapse. Discontinuation of drug therapy after only 2 to 3 months resulted in higher rates of relapse than when therapy was continued for 5 to 12 months. Data show that relapse rates after discontinuation of CBT are significantly less than those after discontinuation of effective pharmacotherapy. Sertraline is the only medication approved for the long-term treatment of SAD, although paroxetine, escitalopram, and venlafaxine prevented relapse.

NONPHARMACOLOGIC THERAPY

Patients should be educated about SAD and support groups. Help group programs that focus on effective communication can benefit people with public-speaking phobia. CBT consists of exposure therapy, cognitive restructuring, relaxation training techniques, and social skills training. Through CBT, patients learn to overcome anxiety in social situations and alter the beliefs and responses that maintain this anxiety. Therapy usually lasts several months and often is conducted in groups. In clinical trials, one-half to two-thirds of patients responded at 12 weeks.

PHARMACOLOGIC THERAPY

Special Populations

SAD can present in children of preschool to elementary school age. If the disorder is not treated, it can persist into adulthood and increase the risk of depression and substance abuse. CBT and social skills training are effective nonpharmacologic therapies in children. Placebo-controlled and open-label trials have provided evidence of efficacy of pharmacotherapy with an SSRI or SNRI in children 6 to 17 years of age. Children and adolescents prescribed an SSRI or SNRI for social anxiety (or for other purposes) should be closely monitored for increased risk of suicidal ideation. Headache, nausea, drowsiness, insomnia, jitteriness, and stomach aches were reported in children receiving antidepressants.

Benzodiazepines should be reserved as the last-line agents in children with SAD. If prescribed, they should be used for the shortest time period possible. The adverse effects of benzodiazepines in children include drowsiness, oppositional behavior, disinhibition, and fatigue. Approximately one-fifth of patients with SAD also suffer from an alcohol use disorder. Many people with SAD report that they use alcohol to cope with anxiety. Paroxetine significantly reduced social anxiety and the frequency and severity of alcohol use in patients with SAD and an alcohol use disorder. MAOIs and benzodiazepines are not appropriate for patients with SAD and alcohol use disorder. SSRIs are the drugs of choice.

Antidepressant Therapy

SSRIs and venlafaxine are beneficial for concurrent depression, and are safe when used in patients with substance abuse. Paroxetine, sertraline, extended-release venlafaxine, and extended-release fluvoxamine are approved for the treatment of generalized SAD, and are considered first-line agents because of efficacy and tolerability (Table 79–8). Controlled trials comparing different

<sup>e</sup>Data from Bandelow et al., Muller et al., Schneier, Stein and Stein, and Vaidhni et al.

SSRs, or SSRIs and an SNRI, demonstrated equivalent efficacy between agents. TCAs are not effective in SAD. Evidence-based guidelines for the treatment of SAD were published by the World Federation of Societies of Biological Psychiatry, the British Association for Psychopharmacology, and the Canadian Psychiatric Association. An algorithm for the pharmacotherapy of generalized SAD appears in Figure 79–3.

**Selective Serotonin Reuptake Inhibitors**

**Efficacy** The efficacy and safety of SSRIs in the treatment of SAD were established in large placebo-controlled trials. Response rates to SSRIs ranged from 50% to 80%.

Patients treated with paroxetine, sertraline, escitalopram, and fluoxetine showed improvement in anxiety and avoidance symptoms and a decrease in disability. SSRIs were well tolerated, and emergent adverse effects were similar to those of depression trials. The onset of effect was delayed 4 to 8 weeks, and maximum benefit was often not observed until 12 weeks or longer. Sertraline was effective in disabled patients suffering from the marked to severe form of generalized SAD. Escitalopram was effective in the treatment of generalized social anxiety. Limited data suggest that citalopram is also effective in treating SAD. Mixed results have been reported for fluoxetine.

**Dosing and Administration** SSRIs should be initiated at doses similar to those used for the treatment of depression and administered as a single daily dose (see Table 79–8). If the patient suffers from comorbid panic disorder, the SSRI dose should be started at one-fourth or one-half of the dose. After 24 weeks of therapy, measures of social anxiety were significantly better with escitalopram 20 mg compared with paroxetine 20 mg. The dose response curve for SSRIs tends to be relatively flat, but individual patients can require higher doses. Increase the dose as tolerated in patients who have not responded after 4 weeks of therapy. When discontinuing an SSRI, the dosage should be tapered monthly (i.e., decreasing sertraline by 50 mg or paroxetine by 10 mg) to reduce the risk of relapse and discontinuation symptoms. Escitalopram produced significantly fewer discontinuation symptoms compared with paroxetine in patients with SAD.

**Venlafaxine**

**Efficacy** Extended-release venlafaxine was significantly better than placebo in improving social interaction, performance, avoidance factors, and some fear factors (e.g., public speaking). Beneficial effects were seen by week 3. Venlafaxine was effective in patients who failed to respond to therapy with SSRIs.

**Adverse Effects** Adverse effects included anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

**FIGURE 79-3.** Algorithm for the pharmacotherapy of generalized social anxiety disorder. Strength of recommendations: **A** = directly based on category I evidence (i.e., meta-analysis of randomized controlled trials [RCT] or at least one RCT); **B** = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); **C** = directly based on category III evidence (i.e., nonexperimental descriptive studies); **D** = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respected authorities), (SSRI, selective serotonin reuptake inhibitor) (Data from Bandelow et al., and Stein and Stein.)
Dosing and Administration Additional therapeutic benefits of venlafaxine above 75 mg/day were not shown. Venlafaxine should be tapered slowly (i.e., decreasing by 37.5 mg/mo) to decrease the risk of relapse during discontinuation.  

Mirtazapine Mirtazapine reduced social anxiety and improved QOL in women with SAD over 10 weeks.  

Alternative Agents  

Benzodiazepines Benzodiazepines are commonly used in the treatment of patients who cannot tolerate or fail to respond to antidepressants. Benzodiazepines are not considered first-line therapy for SAD because of concerns over the adverse effects, potential for dependence, the possibility of rebound anxiety, and ineffectiveness in the treatment of depression. Clonazepam is the most extensively studied benzodiazepine for the treatment of generalized SAD. Clonazepam improved fear and phobic avoidance, interpersonal sensitivity, fears of negative evaluation, and disability measures. Adverse effects included sexual dysfunction, unsteadiness, dizziness, and poor concentration.  

If clonazepam is prescribed, the acute phase of therapy is about 1 month. Patients should be instructed not to decrease or discontinue clonazepam without consulting their clinician because of the risks of rebound anxiety and withdrawal symptoms. Patients on clonazepam for 6 months who were slowly tapered over 5 months maintained their treatment response. Clonazepam should be gradually tapered at a rate not to exceed 0.25 mg every 2 weeks.  

CLINICAL CONTROVERSY  
The role of benzodiazepines in the treatment of SAD is controversial. Some clinicians prescribe benzodiazepines in combination with an antidepressant in the acute management of SAD, then taper the benzodiazepine after 3 to 4 weeks. Recent data indicate that the addition of a benzodiazepine to an SSRI during the acute treatment of SAD does not provide more rapid response, although patients tended to have better outcomes at the end of the trial.  

Anticonvulsants Anticonvulsants are another therapeutic option in SAD. Gabapentin, a nonbenzodiazepine GABA analog, was effective for SAD in a 14-week placebo-controlled trial. The onset of effect occurred within 2 to 4 weeks. Pregabalin was superior to placebo in an 11-week, placebo-controlled trial and the effective dose was 600 mg/day.  

β-Blockers β-Blockers decrease the perception of anxiety by blunting the peripheral autonomic symptoms of arousal (e.g., rapid heart rate, sweating, flushing, and tremor), and they are often used to decrease anxiety in performance-related situations. For patients with specific SAD, 10 to 80 mg of propranolol or 25 to 100 mg of atenolol can be taken one hour before a performance as needed. A test dose should be taken at home before the presentation to assure that β-blockade is sufficient and there are no adverse events. Controlled trials with β-blockers do not support daily use in generalized SAD.  

Treatment Resistance An adequate antidepressant trial usually consists of 8 to 12 weeks (at maximum dosages). Subsequent options include a trial of a second SSRI or extended-release venlafaxine. Some patients experience clinical benefit during the first 4 weeks of therapy. If nonresponsiveness continues, a trial of an alternative agent is warranted.  

There are no data on the choice of treatments if antidepressants fail. Buspirone and clonazepam (in patients without a history of substance abuse) have been used as augmenting agents. The combination of clonazepam and paroxetine over 10 weeks in a placebo-controlled trial did not lead to more rapid resolution of SAD symptoms. However, the group that received the combination therapy had a higher response rate. Atypical antipsychotics and MAOIs are options in treatment-resistant SAD. Quetiapine monotherapy showed a large effect size on the Social Phobia Inventory when compared with placebo. Although phenelzine is effective in 77% of patients with SAD, dietary restrictions, potential drug interactions, and adverse effects (e.g., weight gain and hypertensive crisis) have limited its use. If a patient is switched from another antidepressant to phenelzine, an appropriate washout period should be followed.  

PHARMACOECONOMIC CONSIDERATIONS  
Generalized SAD is associated with lower health-related QOL, a higher rate of lifetime suicide attempts, diminished educational and occupational attainment, and increased use of healthcare resources. SAD was a significant, unrecognized impediment to efforts to reduce welfare reliance and achievement of economic self-sufficiency in women receiving welfare. Early intervention is important in the treatment of SAD. Patients treated with fluvoxamine, sertraline, paroxetine, or escitalopram showed a significantly greater improvement in functioning, disability, and QOL compared with placebo-treated patients. In a relapse prevention study, patients treated with escitalopram experienced a better health-related QOL and more cost-effective therapy than placebo. The acquisition cost of escitalopram was more than offset by a decrease in total costs of care.  

EVALUATION OF THERAPEUTIC OUTCOMES  
The pharmacotherapy of SAD can be monitored in three principal domains: SAD symptoms (e.g., fears and physical symptoms), functionality, and well-being or overall improvement. Response to pharmacotherapy in SAD is defined as a stable, clinically meaningful improvement; patients no longer have the full range of symptoms but typically continue to experience more than minimal symptoms.  

During the acute phase of treatment, patients should be seen weekly while the drug dosage is titrated. Once the patient responds and the dosage is stabilized, the patient can be seen monthly. Many patients report improvement during the first 4 weeks of therapy, but more than a quarter of those who do not have a response at week 8 may have a response at 12 weeks. At each visit, the patient should be asked about adverse effects and improvement in symptoms. The Liebowitz Social Anxiety Scale is a clinician-rated scale of clinical severity and change in SAD for monitoring response. Patients can use the Social Phobia Inventory for self-assessment of SAD symptoms. A complete resolution of symptoms across the three SAD domains that is maintained for 3 months or a Liebowitz Social Anxiety Scale score of less than or equal to 30 points. Patient counseling is important. Patients should be instructed about the gradual onset of effect, when to expect full therapeutic effects, and that long-term therapy is required. When drug therapy is discontinued, the dosage needs to be gradually decreased over several months, and the patient should be seen more frequently to monitor for signs and symptoms of relapse or withdrawal.
It is important to remember that although pharmacotherapy usually leads to improvement in social and occupational functioning, most patients do not achieve a full remission. Many patients require additional treatment, often in the form of CBT.

**TREATMENT**

### Specific Phobia

Specific phobia is considered unresponsive to drug therapy, although highly responsive to CBT. The use of benzodiazepines or paroxetine in patients who failed CBT is supported by limited data. Benzodiazepines can be detrimental in patients with specific phobias treated with CBT.²¹

**CONCLUSIONS**

Anxiety disorders are common in the population and occur concurrently with other psychiatric disorders. The proper management of anxiety disorders begins with the correct diagnosis; not all patients should receive antianxiety agents. Nonpharmacologic interventions often are effective alone or when combined with drug therapy.

There are several subtypes of anxiety disorders, and the diagnosis determines the type of drug and nonpharmacologic intervention selected. Although benzodiazepines remain the drugs of choice for situational anxiety, antidepressants have emerged as first-line therapy for GAD, panic disorder, and SAD. Benzodiazepines are reserved for use in situations requiring immediate anxiety relief during the first 2 to 4 weeks of therapy with a long-term agent such as an antidepressant. Antidepressants, including SSRIs and SNRIs, and the benzodiazepines clonazepam and alprazolam, are used extensively in patients with GAD, panic disorder, and SAD.

The long-term goal of therapy for GAD, panic disorder, and SAD is remission of core anxiety symptoms with no impairment in functionality, minimal anxiety, and no depressive symptoms. Augmentation with atypical antipsychotics show some promise in treatment-resistant cases.

KEY CONCEPTS

1. The short-term goal in posttraumatic stress disorder (PTSD) is reduction in core symptoms, while the long-term goal is remission.

2. Cognitive behavioral therapy and eye movement desensitization and reprocessing are the most effective nonpharmacologic methods to reduce symptoms of PTSD.

3. The selective serotonin reuptake inhibitors or venlafaxine are considered first-line treatment for PTSD.

4. An adequate trial of selective serotonin reuptake inhibitors (SSRIs) in PTSD requires appropriate dosing, titration, and duration of treatment.

5. PTSD compares with depression in the level of disability it imposes on patients.

6. SSRIs are the drugs of choice for the treatment of obsessive-compulsive disorder (OCD).

7. If an inadequate response to an SSRI for OCD occurs after 4 to 6 weeks at the maximum dose, switch to another SSRI.

8. Medication taper can be considered after 1 to 2 years of treatment in patients with OCD.

Current world and local events (e.g., wars, terrorist attacks, earthquakes, kidnappings, interpersonal violence) have placed a renewed focus on posttraumatic stress disorder (PTSD). Initially diagnosed in veterans of war, PTSD is now acknowledged as a significant psychiatric illness in the civilian population and more recently among deployed service personnel of the Afghanistan and Iraq campaigns. It is estimated that approximately 50% of men and 60% of women are exposed to a life-threatening traumatic event. Of these individuals 8.2% of men and 20% of women will develop PTSD. Previous exposure to a trauma and the intensity of response to the event increase the risk of PTSD. Men tend to be assaulted more frequently, but women have a higher rate of PTSD after assault. The incidence of PTSD is equal between men and women after rape (i.e., 50%) and natural disasters (i.e., less than 5%). Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Offspring of Holocaust survivors had a higher lifetime prevalence rate of PTSD compared with a control group.

The estimated lifetime prevalence of PTSD is 6.8% in the U.S. population. Lifetime prevalence of OCD has been estimated at 1.6% in the general population and 2% to 4% in the pediatric population. PTSD is associated with the incidence of trauma. It is estimated that approximately 50% of men and 60% of women are exposed to a life-threatening traumatic event. Of these individuals 8.2% of men and 20% of women will develop PTSD. Previous exposure to a trauma and the intensity of response to the event increase the risk of PTSD. Men tend to be assaulted more frequently, but women have a higher rate of PTSD after assault. The incidence of PTSD is equal between men and women after rape (i.e., 50%) and natural disasters (i.e., less than 5%). Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Offspring of Holocaust survivors had a higher lifetime prevalence rate of PTSD compared with a control group.

The epidemiology of OCD is influenced by age and gender. OCD typically begins early in life, with 20% of cases occurring in childhood, 29% in adolescence, and 49% of cases occurring by age 20. Age of onset has a bimodal distribution with peaks around 10 and 21 years. The onset of illness is earlier in men than in women. Higher rates of other anxiety disorders are reported in first-degree relatives of patients with OCD. Early age of onset has been associated with higher probabilities of comorbid impulse-control, somatoform, eating, and tic disorders. Heredity is stronger when there is an early age of onset or comorbidity with tic disorders.

ETIOLOGY

The exact etiologies of PTSD and OCD are not known. It is likely that abnormalities in several areas of brain functioning interact to cause these chronic anxiety disorders. Genetics may play a role in expression of PTSD and OCD, but environmental factors likely are also involved.

OCD has been characterized as a pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections (PANDAS). In response to streptococcal infection, antibodies are produced in some individuals that temporally precipitate sudden onset or exacerbation of symptoms of OCD. Neuroimaging studies suggest that in these patients the antibodies produce inflammation of the basal ganglia. This leads to increased volumes of the caudate, putamen,
and the globus pallidus, and subsequently to smaller caudate volumes potentially reflective of scarring or atrophy related to streptococcal infection. Although most patients with OCD do not have a streptococcal etiology, an accurate medical history regarding onset of illness is imperative because specific treatment strategies are indicated.

PATHOPHYSIOLOGY

Research findings in the areas of neuroendocrinology, neurobiology, and neuroimaging have advanced a number of theories on the pathophysiology of anxiety disorders. Neuroendocrine changes in the hypothalamic-pituitary-adrenal (HPA) axis are implicated in the pathophysiology of PTSD. As reviewed in the previous chapter (Chapter 79), data from neurochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain (e.g., amygdala, hippocampus, thalamus, and prefrontal cortex). Abnormal function in several neurotransmitter systems, including norepinephrine (NE), y-aminobutyric acid (GABA), glutamate, dopamine (DA), and serotonin (5-HT) may affect the manifestations of anxiety disorders.

NEUROENDOCRINE THEORIES

Neuroendocrine studies provide data that abnormalities occurring pretrauma, during trauma, and posttrauma contribute to PTSD. Normally the immediate reaction to stress occurs as an automatic response from the amygdala to the sympathetic and parasympathetic systems and the HPA axis. The release of corticotropin-releasing factor (CRF) stimulates cortisol secretion from the adrenal gland. Both catecholamines and cortisol levels rise in tandem. Cortisol reduces the stress response by tempering the sympathetic reaction through negative feedback on the pituitary and hypothalamus. These systems return to normal after a few hours.

Recent data implicate a role for the neuropeptides CRF and neuropeptide Y (NPY) in PTSD. Patients with PTSD have a hypersecretion of CRF but demonstrate subnormal levels of cortisol at the time of trauma and chronically. Lower plasma cortisol concentrations were associated with greater severity of PTSD symptoms in nonmilitary patients. Dysregulation of the HPA axis is postulated to be a risk factor for eventual development of PTSD. Higher plasma concentrations of NPY were found in combat-exposed men who did not develop PTSD and could play a role in resiliency.

NEUROCHEMICAL THEORIES

Several neurotransmitters may be involved in the pathophysiology of PTSD. 5-HT, NE, and glutamate are associated with the processing of emotional and somatic contents of memories in the amygdala. The cortex and hippocampus are involved in storing the facts and related cues of memory. The noradrenergic theory posits that the autonomic nervous system of anxious patients is hypersensitive and overreacts to stimuli. The alarm center, the locus ceruleus, releases NE to stimulate the sympathetic and parasympathetic nervous systems. Hyperactive noradrenergic signaling in patients with PTSD is a consistent research finding and includes increased 24-hour catecholamine excretion. Glutamate signaling abnormalities may result in distortion of amygdala-dependent emotional processing under stress. Dysregulation of the processing of sensory input and memories may contribute to the dissociative and hypervigilant symptoms in PTSD. Abnormalities of GABA inhibition may lead to increased awareness or response to stress, as seen in PTSD.

Both 5-HT and DA are implicated in the pathogenesis of OCD. Selective and potent serotonergic reuptake inhibitors have consistently been shown effective for symptoms of the illness. A recent meta-analysis concluded that higher doses of selective serotonin reuptake inhibitors (SSRIs) were associated with improved efficacy in the treatment of OCD. A Cochrane systematic review of 17 studies found that SSRIs were more effective than placebo in treating symptoms of OCD, and that SSRIs were similar to each other in efficacy. DA dysregulation may contribute to some forms of OCD. Neurologic symptoms (e.g., tics) are part of the clinical presentation in some patients with OCD. Tourette’s disorder, a disorder of DA function, is often a concurrent disease. Augmentation with antipsychotic drugs may improve symptoms in patients with OCD who are partially or nonresponsive to SSRI monotherapy.

NEUROIMAGING STUDIES

Neuroimaging studies suggest that certain areas of the brain are altered by psychologic trauma. In PTSD most functional neuroimaging studies have involved the amygdala, ventromedial prefrontal cortex (vmPFC), and hippocampus. Findings of increased activation of the amygdala after trauma-related imagery, sounds, or smells indicate that this structure plays a role in the persistence of traumatic memory. Decreased amygdala activation is correlated with resilience to PTSD and response to cognitive behavioral therapy (CBT). Hypofunctioning of the vmPFC is theorized to prevent extinction in patients with PTSD and is inversely correlated with severity of symptoms. The most consistent findings are decreased hippocampal volumes and N-acetylaspartate levels in patients with PTSD. In twin studies, the unaffected twin of patients with PTSD also demonstrated smaller hippocampi compared with twins without PTSD. These findings suggest that lower hippocampal volumes in patients with PTSD are likely a precursor associated with vulnerability for subsequent development of PTSD.

Neuroimaging studies of two models suggest that dysfunction in the cortical-striatal-thalamic circuits is responsible for impulsive behavior and inability to regulate socially acceptable behaviors. Drugs that decrease hyperactivity in the cortical-striatal-thalamic circuits are theorized to decrease symptoms of OCD.

CLINICAL PRESENTATION

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision classifies anxiety disorders into several categories: generalized anxiety disorder, panic disorder (with or without agoraphobia), social anxiety disorder, specific phobia, OCD, PTSD, and acute stress disorder (ASD). The characteristic features of these illnesses are anxiety and avoidance behavior. Generalized anxiety disorder, panic disorder, and social anxiety disorder are discussed in Chapter 79.
Exposure to a traumatic event is required for a diagnosis of PTSD. The person must have witnessed, experienced, or have been confronted with a situation that involved definite or threatened death or serious injury, or possible harm to themselves or others. The patient’s response to the trauma must include intense fear, helplessness, or horror. Some examples of traumatic events include physical attacks by an intimate partner, road traffic accidents, military combat exposure, natural disasters, being held hostage, child sexual abuse, and witnessing a murder or injury of another.

The resulting PTSD symptoms include persistent reexperiencing of the traumatic event, avoidance of stimuli associated with the trauma, numbing of general responsiveness, and persistent symptoms of hyperarousal. Patients must have at least one reexperiencing symptom, at least three signs or symptoms of persistent avoidance of stimuli associated with the trauma, and at least two symptoms of increased arousal. Symptoms from each category need to be present for longer than 1 month and cause significant distress or impairment in functioning. Most persons diagnosed with PTSD also meet criteria for another mental disorder.

Anxiety and dissociative symptoms (e.g., sense of numbing or absence of emotional responsiveness, derealization, depersonalization, inability to recall important features of the event) emerging within 1 month after exposure to a traumatic stressor are classified as ASD. Symptoms of ASD are experienced during or immediately after the trauma, last for at least 2 days, and resolve within 4 weeks.

The age of onset and course of PTSD are variable. PTSD can occur at any age. The presentation is not predictable because symptoms are related to the duration and intensity of the trauma, the presence of other psychiatric disorders, and how the patient deals with the trauma. Symptoms emerge soon after a traumatic event and either dissipate or chronically persist in survivors. About 95% of patients who recover do so within a year, and 40% have persistent symptoms 6 years later. PTSD co-occurs with mood, anxiety, and substance use disorders. The course of illness is fluctuating, worsening with life stressors.

### Obsessions
- Repetitive thoughts (e.g., feeling contaminated after touching an object, doubting whether the stove was turned off)
- Repetitive images (e.g., recurrent sexually explicit pictures)
- Repetitive impulses (e.g., need for symmetry or putting things in specific order, impulse to shout out obscenities in a church)

### Compulsions
- Repetitive activities (e.g., hand washing, checking, ordering, need to ask, need to confess)
- Repetitive mental acts (e.g., counting, repeating words silently, praying)

Data from American Psychiatric Association and Ballenger et al.

Patients with OCD exhibit a great variety of symptoms on presentation to clinicians. The diversity and oddity of symptoms that manifest can obscure accurate diagnosis and delay appropriate treatment of the disorder. Patients can be secretive about symptoms and purposefully refuse to report symptoms. Patients can present in a seemingly incongruous manner to nonpsychiatrists for other complaints—dermatologists for eczema or chapped skin, pediatricians for parental concerns over a child’s compulsive hand washing, neurologists for tics, or dentists for gum lesions from compulsive teeth brushing.

The diagnostic criteria for OCD requires the presence of obsessions and/or compulsions (although most patients have both) that are severe enough to cause marked distress, to be time-consuming (occupy more than 1 hour per day), or to cause significant impairment in social or occupational functioning. An obsession is a recurrent, persistent idea, thought, impulse, or image that is experienced as intrusive and inappropriate and produces marked anxiety. Common obsessions involve thoughts about contamination (e.g., concern with germs or dirt), repeated doubts, and needing to have things in a particular order.

Individuals must recognize that their obsessions or compulsions are excessive or unreasonable. Obsessions must be acknowledged as products of the individual’s own mind, and attempts must be made to ignore or suppress them. The obsessions produce marked feelings of anxiety and are not simply excessive worry about a real-life situation.

A compulsion is defined as a repetitive behavior or mental act generally performed in response to an obsession. The most common compulsions involve washing and cleaning, counting, checking, and requesting or demanding assurances. Diagnostically, compulsive behavior is not pleasurable and is designed to prevent discomfort or the occurrence of a dreaded event that is often unknown. For example, many patients are obsessed with feelings of doubt (e.g., whether a door was left unlocked), causing them marked distress and leading to repetitive checking (or compulsive behaviors). These behaviors are usually performed according to certain rules or in a stereotyped fashion. Because patients recognize their compulsive behavior as silly or senseless, they become extremely adept at denying symptoms, disguising their rituals, and concealing their illness from friends and family.

Patients with OCD often have concurrent depression, anxiety disorders, and alcohol abuse or dependence. It is a chronic illness in most patients, with severity of symptoms varying in intensity over time. Many patients with OCD have significantly impaired QOL and ability to function. Irritable bowel syndrome has been associated with OCD, with one study reporting that approximately...
35% of patients with OCD met criteria for irritable bowel syndrome compared with 2.5% of a control group. ²⁸

**TREATMENT**

**Posttraumatic Stress Disorder**

**DESIRED OUTCOME**

1. The short-term goal of therapy in the management of PTSD is reduction in core symptoms (i.e., intrusive reexperiencing, avoidance, and hyperarousal). Patients should also have improvements in disability, concurrent psychiatric conditions, and QOL. The long-term goal in PTSD is remission. ²⁹

**GENERAL APPROACH TO TREATMENT**

In general, patients who seek treatment acutely after a trauma and are in intense distress should receive therapy based on their presenting symptoms (e.g., a nonbenzodiazepine hypnotic for difficulty sleeping). Short courses of trauma-focused cognitive behavioral therapy (TFCBT) can be helpful to prevent chronic PTSD in patients who present during the first 3 months of the event. ²¹ If symptoms (e.g., hyperarousal, avoidance, dissociation, sleep difficulties, or depressed mood) persist for 3 to 4 weeks and the patient experiences marked social, occupational, and/or interpersonal impairment, they can be treated with pharmacotherapy, psychotherapy, or both. Many patients with PTSD will improve substantially with pharmacotherapy but retain some symptoms. Treatment regimens usually combine psychoeducation, psychosocial support and/or treatment, and pharmacotherapy. ²³

**NONPHARMACOLOGIC THERAPY**

Psychotherapy can be used when a patient suffers from mild symptoms, in patients who prefer not to use medications, or in conjunction with drugs in patients with severe symptoms to improve response. ²³ Patients who have experienced trauma should be educated that they can experience anxiety, depression, nightmares, and even flashbacks as a normal reaction to the event. ²³ Brief courses of CBT in close proximity to the traumatic event resulted in lower rates of PTSD 3 and 6 months later. ²³ Single-session critical incident stress debriefing was not shown to be effective in preventing development of PTSD and actually can cause harm. ²³

2. Psychotherapies for treating PTSD include stress management, TFCBT and eye movement desensitization and reprocessing (EMDR), and psychoeducation. ²⁹ Short-term reductions in symptoms can be achieved with stress management, group therapy, hypnosis, or psychodynamic therapy. ²⁹ Cognitive and behavioral approaches are more effective than stress management or group therapy to reduce symptoms of PTSD. ³¹ Either TFCBT or EMDR can be used if symptoms are evident for longer than 3 months postevent. ³² Followup studies after a 3-month course of CBT demonstrated continued benefit for 3 to 12 months. ³³ An 8-week comparison found EMDR more successful in maintaining improvements in PTSD scores than fluoxetine or placebo. ³⁴ Psychoeducation includes information about the disease state, treatment options, and avoidance of excessive use of alcohol, nicotine, and other substances of abuse.

**PHARMACOLOGIC THERAPY**

3. Antidepressants are the major pharmacotherapeutic treatment for PTSD. In addition to their efficacy in PTSD, these agents are also effective for concurrent depression and anxiety disorders. SSRIs ³⁶ or venlafaxine are the first-line pharmacotherapy of PTSD. ²⁹ The tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) can also be effective, but they have less favorable side-effect profiles (Table 80–1). Sertraline and paroxetine are both approved for the acute treatment of PTSD, ³⁵, ³⁶ and sertraline is approved for the long-term (i.e., 52 weeks) management of PTSD. ³⁶ A number of drugs can be used as augmentation agents (e.g., antiadrenergic drugs and atypical antipsychotics). ³⁹ Benzodiazepines are not effective for PTSD. ²³, ²⁹ A number of treatment guidelines are published (see Stein et al., 2009 for review). ³⁷ An algorithm from the International Psychopharmacology Algorithm Project for the treatment of PTSD appears in Figure 80–1.

**Special Populations**

Children who experience stress and trauma (e.g., sexual or physical abuse or loss of a parent) are predisposed to develop mood and anxiety disorders. SSRIs are the initial pharmacologic agents of choice in this patient population. Psychotherapy is also a treatment option (e.g., play therapy). ³⁶

**Antidepressant Therapy**

Selective Serotonin Reuptake Inhibitors

SSRIs act pharmacologically to enhance serotonergic functioning. Large prospective studies documented the efficacy of sertraline and paroxetine in the acute management of PTSD. In a 12-week trial sertraline was effective across the spectrum of PTSD-specific, global, and functional outcome measures. Approximately 60% of the patients improved on symptom clusters of arousal and avoidance/numbing but not on reexperiencing. ³⁹ Sixty percent of patients with PTSD receiving a paroxetine dose of 20 mg/day and 54% of patients receiving 40 mg/day responded; response was not related to dose. ⁴⁰ In a flexible-dose trial, paroxetine significantly improved all three PTSD symptom clusters and disability compared with placebo at 12 weeks. ⁴¹ Fluoxetine showed efficacy in a placebo-controlled trial, ⁴² and fluvoxamine ⁴³ and escitalopram ⁴⁴ were efficacious in open trials in acute PTSD. In a comparison between sertraline and citalopram, PTSD symptoms improved significantly in both groups, but sertraline was significantly better in reducing avoidance/numbing than citalopram. ⁴⁵ In general, SSRIs reduced the numbing symptoms of PTSD, whereas other drugs have not. Adverse reactions reported in patients with PTSD treated with SSRIs include gastrointestinal symptoms, sexual dysfunction, insomnia, and agitation. The results

(Data from International Psychopharmacology Algorithm Project.)
of two long-term trials indicate that sertraline (12 months) and fluoxetine (9 months) were effective in preventing relapse.\textsuperscript{45,46}

**Other Antidepressants** The SNRI venlafaxine has shown efficacy in PTSD. In a 12-week, placebo-controlled trial comparing venlafaxine extended-release and sertraline, venlafaxine was effective in reducing the avoidance/numbing and hyperarousal clusters of PTSD, whereas sertraline improved all PTSD symptom clusters.\textsuperscript{47} The remission rates for venlafaxine extended-release were 30.2\% after 12 weeks\textsuperscript{48} and 50.1\% after 6 months.\textsuperscript{49}

Other antidepressants have been studied in controlled trials. Mirtazapine was effective on global ratings of symptoms in 64\% of patients with PTSD in doses up to 45 mg/day and is considered a second-line agent.\textsuperscript{50} Bupropion sustained-release was not effective in patients with chronic PTSD.\textsuperscript{51}

The TCAs amitriptyline and imipramine are considered second-line agents and the MAOI phenelzine is considered a third-line antidepressant if therapeutic trials of SSRIs or venlafaxine have failed. Phenelzine decreased insomnia, nightmares, and flashbacks. TCAs are associated with a higher burden of adverse effects compared with SSRIs (e.g., daytime drowsiness, toxicity in overdose, and poor compliance).\textsuperscript{29}

**Alternative Drug Treatments**

Atypical antipsychotics, α\textsubscript{2}-adrenergic antagonists, antidepressants, mood stabilizers, anticonvulsants, beta-blockers, and azapirones can be used as augmenting agents for persistent symptoms, in cases of partial response to SSRI therapy after 4–6 weeks, or for comorbidities.\textsuperscript{29} Risperidone reduced PTSD symptoms in combat veterans on antidepressants with and without psychosis.\textsuperscript{52} Olanzapine added adjunctively to SSRIs decreased PTSD symptoms and significantly improved sleep compared with placebo. Patients gained an average of 13.2 pounds (6 kg) over the course of the 8-week trial.\textsuperscript{53} Quetiapine reduced core PTSD symptoms over a 8-week period when added to concurrent therapy.\textsuperscript{29}

**Pharmacoeconomic Considerations**

PTSD compares with depression in the level of disability it imposes on patients with the disorder.\textsuperscript{55} Individuals fail to realize their potentials for career development, marriage, and education. Women in a healthcare maintenance organization with high scores on the Posttraumatic Stress Disorder Checklist had more than twice the adjusted total annual median cost ($1,283) of care (i.e., outpatient, specialty care, primary care, pharmacy and mental healthcare costs) than those with a low score ($609).\textsuperscript{56} Treatment with effective pharmacotherapy can improve the QOL and functioning of these patients.\textsuperscript{55}

**Evaluation of Therapeutic Outcomes**

During the acute phase of therapy, patients should be seen weekly for a month and then every other week. During months 3 to 6 of therapy, the patient can be seen monthly, and in months 6 to 12, visits can be extended to every 2 months. On each visit the patient should be asked about previously identified target symptoms of PTSD as well as other symptoms including insomnia, suicidal ideation, anger outbursts, irritability, psychosis, ongoing trauma, and disability. A remission in patients with PTSD is defined as a 70\% or greater reduction in symptoms. Patients who have a 50\% response or greater reduction in symptoms are considered to have an adequate response, while those with a 25\% to 50\% reduction in symptoms are considered partial responders.\textsuperscript{29} Before deciding that a patient is not responsive to pharmacotherapy, the clinician should ensure that the medication trial has been adequate in both dose and duration.

Many patients with PTSD are sensitive to the adverse effects of drugs.\textsuperscript{29} They should be monitored carefully for adverse reactions that can delay the escalation of drug dosages or cause the patient distress. Routine assessment of the metabolic profile is necessary if an atypical antipsychotic is used concurrently.\textsuperscript{29} When pharmacotherapy is discontinued, patients should be seen more frequently and monitored carefully for signs of relapse or withdrawal.

**Obsessive-Compulsive Disorder**

**Desired Outcomes**

Major goals of therapy for OCD include reduction in the frequency and severity of obsessive thoughts and time spent performing compulsive acts. Treatment for OCD generally does not completely

**TREATMENT**

When a patient with PTSD has a partial response to an SSRI the clinician must choose whether to increase the dose of the SSRI, augment with a second agent, or do both simultaneously. There are no published guidelines to direct clinicians with this therapeutic dilemma.

Prazosin can be useful in some patients with PTSD. Prazosin decreased nightmares and sleep disturbances and improved the core PTSD symptoms in daily doses of 1 to 4 mg. Its presumed mechanism of action is reduction of noradrenergic transmission.\textsuperscript{54} Other options for persistent sleep disturbances with less evidence include trazodone, mirtazapine, low dose sedating TCAs, atypical antipsychotics, and zolpidem.\textsuperscript{29}

Anticonvulsants, mood stabilizers, bupropine, and beta-blockers can assist in managing aggression.\textsuperscript{29}

**Dosage and Administration**

**Acute Phase** PTSD symptoms respond slowly to pharmacotherapy, and some patients never experience full resolution. SSRIs should be started 3 to 4 weeks after exposure to a trauma in patients with no improvement in their acute stress response.\textsuperscript{29} The initiation of an SSRI should be at a low dose with gradual titration upward toward antidepressant doses.\textsuperscript{6} Six to 12 weeks is an appropriate duration of antidepressant therapy to determine response.\textsuperscript{29,54}

The dose of sertraline can be increased in weekly intervals by 50 mg/day up to a maximum dosage of 200 mg/day. Paroxetine can be increased by 10 mg/day in weekly intervals to a target dose of 40 mg/day. The dosing of other antidepressants is shown in Table 80-1.

**Continuation Phase** Many patients are undergoing psychotherapy during the continuation phase of therapy, and dosages can vary as patients deal with past traumatic experiences. During this phase symptoms continue to improve, and the maximal drug benefit (i.e., improvement of disability) accrues.\textsuperscript{54} Six-month relapse prevention trials in patients responsive to fluoxetine or sertraline indicate low rates of relapse with SSRI therapy compared with placebo.\textsuperscript{54}
eliminate obsessions or compulsions, but patients can feel remarkably improved with partial resolution of symptoms. Optimal treatment increases psychosocial and occupational functioning and improves overall QOL. Efforts should be made to minimize adverse drug events and prevent drug interactions.

**GENERAL APPROACH TO TREATMENT**

It is important at the outset of therapy to identify and document the specific target symptoms for pharmacotherapy. Rating scales can be used to measure symptom severity at baseline and during treatment to ascertain the degree of improvement. The Yale-Brown Obsessive-Compulsive Scale (YBOCS) is the most widely used clinician-administered scale. A QOL scale can assist the clinician in identifying other areas to target for treatment (e.g., depression and reduced physical well-being). The Food and Drug Administration (FDA) has approved five antidepressants for the management of OCD: clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline. CBT and SSRIs are considered effective first-line treatment modalities. Initial therapy may include CBT alone, SSRI monotherapy, or the combination of CBT and an SSRI, and is based on clinical judgment of symptom severity and patient preferences. CBT alone can be used in cooperative patients who do not desire drug therapy, or those with mild anxiety or depressive symptoms. Patients unable to participate in CBT or with a prior history of medication therapy response should be treated with SSRI monotherapy. Combined CBT and SSRIs is recommended in patients with failure on an SSRI alone or those with severe OCD. If a combination of CBT and an SSRI is unsuccessful, another SSRI should be tried before augmentation therapy. If there is no response or partial response to combined CBT and three adequate antidepressant trials (one of which is clomipramine), augmentation with another drug and more intensive CBT can be tried. Augmentation with antipsychotics has proven efficacious in patients with partial response.

Table 80–2 is a summary of key points from the treatment guidelines for OCD. Although some OCD symptoms can improve over the first few weeks of therapy, an adequate trial of any medication is considered to be 8 to 12 weeks at maximum tolerated dosage.

**NONPHARMACOLOGIC TREATMENTS**

A number of nonpharmacologic treatments are effective for OCD. CBT with behavioral techniques (e.g., exposure and response prevention [ERP], psychodynamic psychotherapy, and psychoanalysis) are the most common initial nonpharmacologic treatments of choice. Initially, 13-20 sessions are recommended. Clinicians can use motivational interviewing techniques to assist patients with treatment acceptance.

Other options are transcranial magnetic stimulation (TMS), deep brain stimulation (DBS), and ablative neurosurgery. DBS is FDA-approved as a humanitarian device for severe, treatment-resistant OCD. TMS and DBS should not be used alone as first-line treatments but may be added to CBT or used in refractory patients. Surgery should be reserved for rare cases. Effects of ERP have been reported to last up to two years.

**PHARMACOLOGIC THERAPY**

Practice Guidelines for the treatment of patients with OCD were published by the American Psychiatric Association. SSRIs are considered to be the drugs of choice for OCD. While not FDA approved, escitalopram has also shown efficacy in reduction of OCD symptoms. Clomipramine, a TCA with strong 5-HT reuptake inhibition, is also FDA approved for the treatment of OCD. Clomipramine has an active metabolite, desmethylclomipramine, which inhibits norepinephrine reuptake. Meta-analytic findings of greater efficacy of clomipramine than SSRIs are not consistent with comparative trial data.

**Alternative Drug Treatments**

Recent studies have examined the use of ondansetron, dextroamphetamine, caffeine, and D-cycloserine as possible augmentation agents in refractory OCD patients with mixed results. A study of ondansetron found 9 of 14 patients with OCD responded to ondansetron augmentation therapy. In a study of caffeine and dextroamphetamine augmentation, YBOCS score decreases ranged...
from 20% to 80% in the dextroamphetamine group and 27% to 89% in the caffeine group. The number of exposure sessions necessary in patients treated with D-cycloserine was reduced compared with placebo initially. These alternative treatments are reserved for refractory patients.

Special Populations

Children and Adolescents OCD affecting children and adolescents is prevalent. There are symptom and treatment similarities and differences between OCD developing earlier in life and that which develops later. Younger patients exhibit poorer insight regarding obsessions, have more obsessions involving fear of harm and separation, and possess more rituals involving family members. CBT provided in the group setting has been shown to be effective and is an alternative to individual CBT or medication treatment. CBT weekly or daily and including family members has been effective and is an alternative to individual CBT or medication treatment. 67

Elderly Case reports and anecdotal information suggest that the antipsychotics are likely to be equally effective in the elderly and in younger individuals. Elderly women. In a multiple-dose study in the elderly, the minimum plasma clearance of paroxetine was 40% lower than in a group of younger individuals. Clearance of risperidone, quetiapine, and olanzapine may be helpful. Typical antipsychotics are generally not recommended because of an increased likelihood of extrapyramidal symptoms. Risperidone, quetiapine, and olanzapine augmentation has the most evidence with response rates in the range of 40% to 50%.

Antidepressant Therapy

Serotonergic Antidepressants The only potent 5-HT reuptake inhibitors consistently demonstrating efficacy in controlled trials are the TCA clomipramine and the SSRIs fluoxetine, fluvoxamine, paroxetine, and sertraline. Forty percent to 60% of patients with OCD respond to a serotonergic antidepressant. Improvement in symptoms is incomplete, and ranges from 20% to 40%. Most patients continue to have symptoms that limit their functioning. Ten to 12 weeks constitute an adequate treatment period.

Current evidence indicates that 5-HT is important for the anti-obsessional effects of medication. SSRIs and clomipramine inhibit 5-HT reuptake into the presynaptic neuron. Inhibiting reuptake of 5-HT makes more 5-HT available to postsynaptic receptors and reduces formation of the 5-HT metabolite 5-hydroxyindoleacetic acid. Although other antidepressants, such as imipramine and amitriptyline, inhibit 5-HT reuptake, they are less potent and selective than SSRIs. Prolonged exposure to increased amounts of 5-HT after chronic antidepressant treatment (2–3 weeks) leads to altered responsiveness of postsynaptic 5-HT receptors or presynaptic autoregulatory receptors that govern 5-HT release in specific brain regions. An improvement in obsessional symptoms may correlate with plasma concentrations of clomipramine but not desmethyloclomipramine, the metabolite of clomipramine with less selectivity for 5-HT reuptake inhibition.

Most experts agree that SSRIs are better tolerated than clomipramine. SSRIs are less likely to cause cardiovascular, sedative, anticholinergic, and weight-gain side effects. Clomipramine is less likely than SSRIs to cause insomnia, akathisia, nausea, and diarrhea.

Antidepressant side effects can be more severe when larger doses are used and with faster dose escalation. Tolerance to antidepressant adverse effects often develops over 6 to 8 weeks of treatment, and tolerance is more likely to develop to nausea, diarrhea, sedation, diminished libido and/or orgasm, anxiety, restlessness, insomnia, and anticholinergic side effects than to akathisia.

Pharmacokinetics Clomipramine is rapidly absorbed following oral administration. Maximum plasma concentrations occur within 3 to 8 hours. It is highly protein-bound (greater than 90%) in the blood and has a half-life of 15 hours. The drug is metabolized to desmethyloclomipramine, which is pharmacologically active. The pharmacokinetics of SSRIs are discussed in Chapter 77.

Efficacy SSRIs are effective in the treatment of OCD. Well-designed trials comparing these medications with placebo, head-to-head comparative trials, and meta-analyses have established that fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram are equally effective and that clomipramine may be somewhat more effective.

Other Antidepressants Venlafaxine, which acts as a serotonin and norepinephrine reuptake inhibitor, may be effective for OCD.

Augmentation with Antipsychotics Augmentation of SSRI treatment with low doses of risperidone, quetiapine, or olanzapine may be helpful. Typical antipsychotics are generally not recommended because of an increased likelihood of extrapyramidal symptoms.

Pregnancy Risk-benefit analysis should be made by practitioners when deciding to use pharmacotherapy options during pregnancy. The use of SSRIs in pregnancy and lactation is discussed in the chapter on depression (Chapter 77).
Dosage and Administration Table 80–3 summarizes dosing guidelines for SSRIs and clomipramine. If there is inadequate response to an average dose, then it should be incrementally increased to the maximum dose within 5 to 9 weeks from the start of treatment. If there is an inadequate response after 4 to 6 weeks at the maximum dose, then another SSRI should be tried. Eight to 12 weeks is considered an adequate trial before changing to another drug or augmenting with another agent.

Although the appropriate maintenance dose of antidepressants is unknown, it is notable that one investigator was successful in reducing the dose of clomipramine from a mean of 270 mg/day to 165 mg/day in the maintenance phase.

PHARMACOECONOMIC CONSIDERATIONS

The annual outpatient direct cost for treatment of OCD in the United States in 1995 was $5.1 billion. In 1990, the total cost to the economy was $8 billion, which included expenditures for direct ($2.1 billion) and indirect costs. Direct costs included costs of hospitalization, outpatient professional services, and drugs. Indirect costs were costs associated with lost productivity, work loss, early retirement, and absenteeism. As OCD frequently has its onset in childhood or adolescence, loss of income over a lifetime is substantial.

Another pharmacoeconomic consideration that impacts the provision of optimal treatment for patients with OCD relates to inability to pay for nonpharmacologic therapy. Although CBT has been shown to be a very effective modality, very often the patient cannot afford this therapy or does not have medical insurance that helps pay the associated costs.

EVALUATION OF THERAPEUTIC OUTCOMES

Target symptoms of OCD should be monitored closely. The degree of response can indicate a need to modify dosage, change drug, or augment therapy. Rating scales can be used to monitor symptom response to therapy for OCD (e.g., YBOCS) and changes in QOL. The clinician should inquire about and address problematic adverse effects (including the emergence of suicidal ideation) reported by the patient. Changes in social and occupational functioning should be assessed.

Patients older than 40 years of age should receive a pretreatment electrocardiogram before starting clomipramine. In patients with liver disease, baseline and periodic liver function tests are recommended when clomipramine is used. Patients receiving clomipramine who develop fever and sore throat should have leukocyte and differential white blood cell counts assessed to evaluate for agranulocytosis.

After patients have responded to the acute phase of treatment, treatment gains are maintained with maintenance-phase strategies. Monthly follow-up visits are recommended for at least 3 to 6 months, and a medication taper can be considered after 1 to 2 years of treatment. Medication should not be rapidly discontinued, and booster CBT sessions can reduce the risk of relapse when medication is withdrawn. The drug dosage can be decreased by 10% to 25% every 1 to 2 months with careful observation for symptom relapse. Some patients require lifelong medication therapy.

CONCLUSIONS

The past decade has brought a renewed interest in the recognition and management of PTSD. Healthcare workers are sensitized to the devastating effects that PTSD can have on patient functioning and QOL. Adequately detecting and appropriately managing PTSD is important to improving the lives of patients who suffer from this illness. Data on the efficacy of SSRIs, SNRIs, and various augmenting agents support their use in achieving treatment remission. SSRIs are the first-line pharmacotherapy of PTSD and OCD. Research in OCD has resulted in new pharmacologic treatment strategies, especially with augmentation therapies.

ABBREVIATIONS

ASD: acute stress disorder
CBT: cognitive behavioral therapy
CRF: corticotrophin-releasing factor
DA: dopamine
DBS: deep brain stimulation

CHAPTER 81
Sleep Disorders
JOHN M. DOPP AND BRADLEY G. PHILLIPS

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

1. Common causes of insomnia include concomitant psychiatric disorders, significant psychosocial stressors, excessive alcohol use, caffeine intake, and nicotine use.
2. Good sleep hygiene, including relaxing before bedtime, exercising regularly, establishing a regular bedtime and wake-up time, and discontinuing alcohol, caffeine, and nicotine, alone and in combination with drug therapy, should be part of patient education and treatments for insomnia.
3. Long-acting benzodiazepines should be avoided in the elderly.
4. Benzodiazepine tolerance and dependence are avoided by using low-dose therapy for the shortest possible duration.
5. Obstructive sleep apnea may be an independent risk factor for the development of hypertension. When hypertension is present, it is often refractory to drug therapy until sleep-disordered breathing is alleviated.
6. Nasal continuous positive airway pressure is the first-line therapy for obstructive sleep apnea, and weight loss should be encouraged in all obese patients.
7. Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness and cataplexy.
8. Short-acting benzodiazepine receptor agonists or melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.
9. Dopamine agonists are effective for restless legs syndrome and have replaced levodopa as first-line therapy.

INTRODUCTION TO SLEEP

SLEEP CYCLES

Sleep is divided into two phases: nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Humans typically experience four to six cycles of NREM and REM sleep, with each cycle lasting between 70 and 120 minutes. There are four stages of NREM sleep. Healthy sleep will typically progress through the four stages of NREM sleep prior to the first REM period. From wakefulness, sleep typically progresses quickly through stages 1 and 2. Stage 1 of NREM sleep is the stage between wakefulness and sleep, and individuals describe this experience as being awake, being drowsy, or being asleep. During stages 3 and 4 NREM, both metabolic activity and brain waves slow. This slow-wave sleep occurs most frequently early in the sleep period. Stage 3 and stage 4 sleep are called delta sleep, as the sleep is characterized by high-amplitude slow activity known as delta waves (0.5–3 Hz). In this stage eye movements are absent, and muscle tone is atonic.

REM sleep involves a dramatic physiologic change from NREM sleep, to a state in which the brain becomes electrically and metabolically activated. REM occurs in bursts and is accompanied by a 62% to 173% increase in cerebral blood flow, generalized muscle atonia, bursts of bilateral rapid eye movements, poikilothermia, dreaming, and fluctuations in respiratory and cardiac rate. REM cycles tend to lengthen in the later stages of the sleep cycle.

CIRCADIAN RHYTHM

At birth human infants spend up to 20 hours a day sleeping. At 3 to 6 months of age there is a differentiation between REM and NREM sleep. By age 3 the ultradian sleep–wake rhythm changes to a circadian pattern. The suprachiasmatic nucleus of the brain serves as the biologic clock and paces the circadian rhythm. Although the length of a day is 24 hours, in environments devoid of light cues, the sleep–wake cycle lasts 24.2 hours. In midlife, there is a gradual decline in sleep efficiency and sleep time. The elderly have lighter and more fragmented sleep, with intermittent arousals, shifts in the sleep stages, and a gradual reduction of slow wave sleep.

NEUROCHEMISTRY

The neurochemistry of sleep is complex as sleep cannot be localized to either a specific area of the brain or a neurotransmitter. NREM sleep appears to be controlled by the basal forebrain, the area surrounding the solitary tract in the medulla and the dorsal raphe nucleus, which is primarily serotonergic. Sleep is reduced when there are decreases in serotonin or destruction of the dorsal raphe nucleus in the brainstem, which contains most of the
brain’s serotonergic bodies. REM sleep appears to be turned on by cholinergic cells in the mesencephalic, medullary, and pontine gigantocellular regions. REM sleep appears to be turned off by the dorsal raphe nucleus, the locus coeruleus, and the nucleus parabra- chialis lateralis, the latter two of which are primarily noradrenergic. The ascending reticular activating system and the posterior hypothalamus facilitate arousal and wakefulness. Dopamine has an alerting effect; decreases in dopamine promote sleepiness. Neurochemicals involved in wakefulness include norepinephrine and acetylcholine in the cortex and histamine and neuropeptides such as substance P and corticotropin-releasing factor in the hypothalamus.

**POLYSOMNOGRAPHY**

Sleep is typically measured and observed in sleep laboratories using an electroencephalogram (EEG), electro-oculograms of each eye, electrocardiogram, electromyogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitor. This study is named polysomnography (PSG) and is used to assess and record variables that characterize sleep and aid in diagnosis of sleep disorders. Variables obtained during PSG include sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations.

**CLASSIFICATION OF SLEEP DISORDERS**

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) classifies sleep disorders into four categories based on etiology and requires a minimum of 1 month before a sleep disorder can be diagnosed. Primary sleep disorders are those disorders in which there is no other etiology (mental disorder, substance-related disorder, or medical condition) responsible for the disorder. Primary sleep disorders appear to be based on an endogenous abnormality of the sleep–wake cycle, or circadian rhythm, and they are divided into dyssomnias (abnormality in the amount, quality, or timing of sleep) or parasomnias (abnormal behavioral or physiologic events associated with sleep, e.g., sleepwalking and REM behavior disorder). Dyssomnias include sleep disorders such as insomnia, narcolepsy, obstructive sleep apnea, and circadian rhythm disorders.

**INSOMNIA**

Insomnia is the most common complaint in general medical practice. It causes distress, frequently because of a fear or a feeling of not being able to fall asleep, and can impair work-related productivity because of daytime fatigue or drowsiness. Insomnia is subjectively characterized as a complaint of difficulty falling asleep, difficulty maintaining sleep, or experiencing nonrestorative sleep. Insomnia lasting two or three nights because of jet lag, for example, is considered to be transient insomnia, whereas short-term insomnia usually resolves in less than 3 weeks. Insomnia, according to the DSM-IV-TR, is considered to be chronic when it lasts longer than 1 month.

**Epidemiology**

Primary insomnia usually begins in early or middle adulthood and is rare in childhood or adolescence. More than 50% of the population complains of insomnia in their lifetime. A 1-year prevalence study of insomnia in the United States reports that one third of the individuals surveyed complained of insomnia, and 17% reported that the symptoms were serious. Conservative estimates of chronic insomnia range from 9% to 12% in adulthood and up to 20% in the elderly. Although young adults are more likely to complain that they have difficulty falling asleep, middle-aged and elderly adults are more likely to complain that they have middle-of-the-night awakening or early morning awakening. Women complain of insomnia twice as frequently as men. Individuals who are elderly, unemployed, separated, or widowed, and those with a lower socioeconomic status reported a significantly higher incidence of insomnia than the general population. Forty percent of individuals with insomnia also had a concurrent psychiatric disorder (anxiety, depression, or substance abuse). Despite the prevalence of insomnia, only 5% of individuals seek medical attention for management of their insomnia. Approximately 10% to 20% of those with insomnia use nonprescription drugs or alcohol to self-treat. Of the 3% of the population who are prescribed sedative–hypnotics for insomnia, 11% report use exceeding 1 year.

**Differential Diagnosis**

Primary insomnia is considered to be an endogenous disorder caused by either a neurochemical or a structural disorder affecting the sleep–wake cycle. Individuals with primary insomnia can be light sleepers who are easily aroused by noise, temperature, or anxiety. Some studies suggest that primary insomnia is a “hyperarousal state,” in that insomnia patients have increased metabolic rates compared with controls and thus take longer to fall asleep. Comorbid insomnia is frequently a symptom or manifestation of another medical disorder. Evaluation of patients with a complaint of transient or short-term insomnia should focus on recent stressors, such as a separation, a death in the family, a job change, or college exams.

TREATMENT

Insomnia

Therapeutic management of insomnia is initially based on whether the individual has experienced a transient, short-term, or chronic sleep disturbance. Clinical history should assess the onset, duration, and frequency of the symptoms; effect on daytime functioning; sleep hygiene habits; and history of previous symptoms or treatment. Management of all patients with insomnia should include identifying the cause of the insomnia, patient education on sleep hygiene, and stress management. Any unnecessary pharmacotherapy should be eliminated. Transient insomnia, which occurs as a result of an acute stressor, is expected to resolve quickly and should be treated with good sleep hygiene and careful use of sedative-hypnotics. Short-term insomnia, associated with situational, personal, or medical stress can be treated similarly. Chronic insomnia requires careful assessment for possible underlying medical causes, nonpharmacologic techniques, and careful use of sedative-hypnotics.

NONPHARMACOLOGIC THERAPY

In many cases insomnia can be treated without sedative-hypnotics. Education about normal sleep and habits for good sleep hygiene are often sufficient interventions. Nonpharmacologic interventions for insomnia frequently consist of short-term cognitive-behavioral therapies, most commonly stimulus control therapy, sleep restriction, relaxation therapy, cognitive therapy, paradoxical intention, and education on good sleep hygiene (Table 81–2).

In patients age 55 and older, research indicates that cognitive behavioral therapy may be more effective than pharmacologic therapy at improving certain measures of insomnia.

PHARMACOLOGIC THERAPY

Miscellaneous Agents

Antihistamines exhibit sedating properties and are included in many over-the-counter sleep agents. They are effective in the treatment of mild insomnia and are generally safe. Diphenhydramine and doxylamine are more sedating than pyrilamine. Increasing the dose of antihistamines will not produce a linear increase in response. The safety and efficacy of antihistamines over placebo have been documented in several studies. Antihistamines are considered to be less effective than benzodiazepines, and they have the disadvantages of anticholinergic side effects, which are especially troublesome in the elderly.

Antidepressants are alternatives for patients with nonrestorative sleep who should not receive benzodiazepines, especially those who have depression, pain, or a risk of substance abuse. Using antidepressants for insomnia without depression is common but not well studied, and the doses used for treating insomnia are not effective antidepressant doses. Sedating antidepressants such as amitriptyline, doxepin, and nortriptyline are effective for inducing sleep continuity, although daytime sedation and side effects can be significant. Anticholinergic activity, adrenergic blockade, and cardiac conduction prolongation can be problematic, especially in the elderly and in overdose situations. Mirtazapine is a sedating antidepressant that may help patients sleep, but it may also cause daytime sedation and weight gain.

Trazodone in doses of 25 to 100 mg at bedtime is sedating and can improve sleep continuity. Trazodone is popular for the treatment of insomnia in patients prone to substance abuse, as dependence is not a problem. Trazodone is frequently used in patients with selective serotonin reuptake inhibitor (SSRI) and bupropion-induced insomnia. Caution should be used to avoid serotonin syndrome when used in these combinations. Other side effects include carryover sedation and α-adrenergic blockade. Orthostasis can occur at any age, but it is more dangerous in the elderly. Priapism is a rare but serious side effect.

Ramelteon is a melatonin receptor agonist approved for the treatment of sleep onset insomnia. Ramelteon is selective for the MT1 and MT2 melatonin receptors that are thought to regulate the circadian rhythm and sleep onset. The recommended dose is 8 mg taken at bedtime to induce sleep. Although generally well tolerated, the most common adverse events reported are headache, dizziness, and somnolence. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse.

Valerian is an herbal sleep remedy that has been studied for its sedative-hypnotic properties in patients with insomnia. The mechanism of action is not fully understood but may involve increasing concentrations of γ-aminobutyric acid (GABA). The recommended dose for insomnia ranges from 300 to 600 mg. An equivalent dose of dried herbal valerian root is 2 to 3 g soaked in 1 cup of hot water for 20 to 25 minutes.

CLINICAL CONTROVERSY

Pharmacologic treatment is indicated for transient and short-term insomnia. Historically, the use of sedative hypnotic agents for greater than 1 month was frowned on and discouraged in fear of fostering drug dependence. Experts now agree that clinicians should encourage hypnotic therapy using the lowest effective dose for the shortest duration possible. However, long-term use of hypnotics is not contraindicated unless the patient has another contraindication (e.g., history of substance abuse, pregnancy, etc.).

CLINICAL CONTROVERSY

The over-the-counter supplement melatonin is a popular treatment for insomnia. Although melatonin has demonstrated efficacy for inducing sleep, its use for the treatment of insomnia is not well supported by clinical studies. Further research is needed before melatonin can be recommended for the treatment of insomnia.

Benzodiazepine Receptor Agonists

The most commonly used treatments for insomnia have been the benzodiazepine receptor agonists. All benzodiazepine receptor agonists are effective as sedative-hypnotics and are FDA labeled for the treatment of insomnia (Table 81–3). The FDA recently required benzodiazepine receptor agonist labeling to include a caution regarding anaphylaxis, facial angioedema, and complex sleep behaviors (e.g., sleep driving, phone calls, sleep eating, etc.). The benzodiazepine receptor agonists consist of the newer nonbenzodiazepine GABA<sub>A</sub> agonists and the traditional benzodiazepines. All benzodiazepine receptor agonists bind to GABA<sub>A</sub> receptors in the brain, resulting in stimulatory effects on GABAergic transmission and hyperpolarization of neuronal membranes. Traditional benzodiazepines have sedative, anxiolytic, muscle relaxant, and anticonvulsant properties; newer nonbenzodiazepine GABA<sub>A</sub> agonists possess only sedative properties.

**Benzodiazepine Hypnotics**

Benzodiazepines relieve insomnia by reducing sleep latency and increasing total sleep time. Benzodiazepines increase stage 2 sleep while decreasing REM, stage 3, and stage 4 sleep. Rebound insomnia increases after benzodiazepine discontinuation, which is more frequent after high doses of triazolam, even when ingested intermittently. The lowest effective dosage should be used to minimize rebound insomnia and avoid adverse effects on memory.

Benzodiazepine half-lives are prolonged in older patients, increasing the potential for drug accumulation and the incidence of CNS side effects, including prolonged sedation and cognitive and psychomotor impairment. Benzodiazepine receptor agonists with long elimination half-lives are generally not first-line agents in these patients. There is an association between falls and hip fractures and the use of benzodiazepines with long elimination half-lives; thus flurazepam and quazepam should be avoided in elderly patients.

<sup>a</sup> Time to peak plasma concentration.
<sup>b</sup> Half-life of parent drug.
<sup>c</sup> N-desalkylflurazepam, mean half-life 47 to 100 hours.

Anterograde amnesia, an impairment of memory and recall of events occurring after the dose is taken, has been reported with most benzodiazepine receptor agonists. Rebound insomnia, characterized by increased wakefulness beyond baseline amounts that last for 1 to 2 nights after abrupt discontinuation, occurs with benzodiazepine receptor agonists. Rebound insomnia occurs more frequently after high doses of triazolam, even when ingested intermittently. The lowest effective dosage should be used to minimize rebound insomnia and avoid adverse effects on memory.

**Nonbenzodiazepine GABA<sub>A</sub> Agonists**

Zolpidem, zaleplon, and eszopiclone are nonbenzodiazepine hypnnotics that selectively bind to GABA<sub>A</sub> receptors and effectively induce sleepiness. Zolpidem, an imidazopyridine chemically unrelated to benzodiazepines or barbiturates, has a duration of action of 6 to 8 hours. It is comparable in efficacy to benzodiazepine hypnotics and is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time. It does not appear to have significant effects on next-day psychomotor performance. A sustained release formulation of zolpidem is now available that is effective at increasing total sleep time and reducing wakefulness after sleep onset without significant carryover sedation.

The safety and efficacy of zolpidem for insomnia is similar to that of the benzodiazepines. Zolpidem is less disruptive of sleep stages than benzodiazepines. Adverse effects are dose related and can include drowsiness, amnesia, dizziness, headache, and gastrointestinal complaints. Several cases of brief psychotic reactions have been reported in women, and recent reports of sleep-eating during zolpidem therapy have caused significant weight gain. The recommended daily dose of zolpidem is 10 mg or 5 mg in elderly patients and those with hepatic impairment. The dosage can be increased to 20 mg per night. Because food decreases its absorption, zolpidem should be taken on an empty stomach.

Zaleplon is a pyrazolopyrimidine and has a rapid onset of action and a half-life of 1 hour, and it is metabolized to inactive metabolites. It is effective for decreasing time to sleep onset but not for reducing nighttime awakening or for increasing total sleep time. Because of its short half-life, zaleplon has no effect on next-day

**Pharmacokinetics** The choice of a particular benzodiazepine can be based on its pharmacokinetic profile. When used as a single dose, extent of distribution and elimination half-life are important in predicting the duration of action. However, after multiple doses, the elimination half-life and formation of active metabolites determine the extent of drug accumulation and resultant clinical effects.

**Adverse Effects** Side effects are dose dependent and vary according to the pharmacokinetics of the individual benzodiazepine. High doses with long or intermediate elimination half-lives have a greater potential for producing daytime sedation, psychomotor incoordination, decreased concentration, and cognitive deficits. Tolerance to benzodiazepine hypnotic effects develops sooner with triazolam (after 2 weeks of continuous use) than with other benzodiazepine hypnotics. Most traditional benzodiazepines maintain hypnotic efficacy for 1 month. However, tolerance can develop with time. Rapidly eliminated benzodiazepines have less potential for daytime sedation.
Patients should be instructed to keep a sleep diary. The diary requires daily recording of bedtime, wake time, latency of sleep onset, number and duration of awakenings, medication ingestion, naps, and an index of sleep quality. For patients with chronic insomnia, possible medical, psychiatric, and pharmacologic causes should be identified and managed. Patients with insomnia should receive education about possible medication side effects and their management. Prescriptions for benzodiazepine receptor agonists should be accompanied by printed information and verbal counseling on precautions.

Clinicians should educate patients about the concepts of tolerance, withdrawal, and rebound insomnia. Tolerance and dependence can be avoided by using hypnotics at the lowest possible dose, intermittently, and for the shortest duration possible. Patients should receive instruction on the initiation of therapy about frequency of drug use and the expected duration of therapy, to help prevent development of dependence. Withdrawal symptoms can be diminished by tapering the dosage gradually.

**EVALUATION OF THERAPEUTIC OUTCOMES**

An algorithm for the evaluation and treatment of sleep disorders is shown in Figure 81–1. Patients with short-term or chronic insomnia should be evaluated after 1 week of therapy to assess for drug efficacy, adverse effects, and adherence to nonpharmacologic recommendations.

**SLEEP APNEA**

Approximately 15 million Americans have sleep-disordered breathing. The prevalence of sleep apnea in the U.S. adult population is 4% in males and 2% in females. It appears to be more common in African Americans and less common in Asian populations. Sleep apnea also occurs in children and adolescents. It is characterized by repetitive episodes of cessation of breathing during sleep followed by blood oxygen desaturation and brief arousal from sleep to restart breathing. As a result, individuals with sleep apnea experience fragmented sleep, poor sleep architecture, and periods of apnea...
and hypopnea. Polysomnography (PSG) is used to diagnose and quantify sleep apnea as central, obstructive, or mixed. Central sleep apnea (CSA) involves impairment of the respiratory drive, whereas obstructive sleep apnea (OSA) is caused by upper airway collapse and obstruction. Patients with mixed sleep apnea experience both central and obstructive sleep apnea. Severity of sleep apnea is determined by the number of apneas (total cessation of airflow) and hypopneas (partial airway closure with blood oxygen desaturation) episodes documented by PSG, and is expressed by calculating the respiratory disturbance index (RDI). Mild sleep apneics have an RDI of between 5 and 15 episodes per hour, moderate 15 to 30, whereas individuals with severe OSA can exhibit more than 30 episodes per hour.

Sleep apnea can affect behavior, cognitive abilities, and systemic disease. Neurocognitive sequelae are important factors in motor vehicle accidents, loss of work-related productivity, and personality changes. Alleviation of sleep disordered breathing can have a beneficial impact on both cardiovascular and neurobehavioral conditions.

**OBSTRUCTIVE SLEEP APNEA**

OSA is characterized by partial or complete closure of the upper airway, posterior from the nasal septum to the epiglottis, during inspiration. The reason for the loss of upper airway patency is not fully understood and is likely caused by several competing factors. Anatomical factors including neck obesity, narrow airway, and fixed upper airway lesions (e.g., polyps, enlarged tonsils) can narrow the upper airway. Intraluminal negative pressure generated during each inspiration also promotes collapse of the upper airway that competes with dilating forces, primarily the pharyngeal dilator muscle. Acromegaly, amyloidosis, and hypothyroidism as well as neurologic conditions that impair upper airway muscle tone may cause OSA. The hallmarks of OSA are witnessed apneas, gasping, or both. Other recognized signs, symptoms, and considerations of sleep apnea include obesity, snoring, hypertension, daytime sleepiness, and family history.

OSA is increasingly linked to cardiovascular and cerebrovascular morbidity and mortality, independent of other risk factors. Individuals with OSA are at risk for developing hypertension, and when hypertension is present, it is often resistant to drug therapy. Alleviation of sleep disordered breathing (with nasal continuous positive airway pressure) can improve blood pressure and attenuate some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.

**TREATMENT**

**Obstructive Sleep Apnea**

In the absence of an underlying cause (e.g., hypothyroidism, acromegaly), alleviation of sleep disordered breathing is the primary goal of treatment. Nonpharmacologic measures are the treatments of choice. There is no drug therapy for OSA. However, medications that worsen sleep should be avoided. Practice parameters for the treatment of OSA have been published by the American Academy of Sleep Medicine.

**NONPHARMACOLOGIC THERAPY**

**Positive Airway Pressure**

Nasal positive airway pressure (PAP) during sleep is the standard treatment for most patients with OSA. PAP produces a positive pressure column in the upper airway using room air to maintain patency. A flexible tube connects the PAP machine to a mask that covers the nose.

PAP delivery may be continuous (CPAP) or bilevel, providing a reduced applied pressure during expiration. During PSG, the pressure setting is increased (up to 20 cm H₂O) until sleep-disordered breathing is eliminated. Barriers to PAP adherence, such as ill-fitted mask and nasal dryness, can be managed. PAP nonadherence for one night results in a complete reversal of the gains made in daytime alertness. In the clinical setting, poor PAP adherence may impact blood pressure control and management in patients with OSA and hypertension.

**Weight Reduction**

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. OSA can itself predispose to weight gain and in obese patients with mild OSA weight loss alone can be effective. Individuals who are morbidly obese and have severe OSA can undergo gastric stapling for weight loss.

**Surgery**

Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. This is not a first-line option because it is invasive. In very severe cases tracheostomy can be necessary. This procedure can be indicated for select individuals that are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (e.g., less than 70%), or have significant cardiac arrhythmias associated with their OSA.

**Other Therapies**

For individuals that experience OSA only during certain sleep positions (e.g., on their back), positional therapies can be effective alone but are usually used in conjunction with PAP therapy. Oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. These therapies should be considered when PAP therapy cannot be tolerated.

**PHARMACOLOGIC THERAPY**

The most important pharmacologic intervention is the avoidance of all CNS depressants (e.g., alcohol, hypnotics) and drugs that promote weight gain. Weight gain worsens OSA. CNS depressant use is potentially lethal as it reduces the brain’s reflex ability to cause a mini- arousal and resume breathing. In addition, certain CNS depressants can relax airway muscles, promoting upper airway collapse. Medications that can cause rhinopharyngeal inflammation and cough as a side effect of therapy (i.e., ACE inhibitor) may also worsen sleep-disordered breathing.

There is no drug therapy for OSA. In clinical trials, serotoninergic agents (e.g., fluoxetine, paroxetine), tricyclic antidepressants (TCAs) (i.e., imipramine, protriptyline), respiratory stimulants (aminophylline and theophylline), medroxyprogesterone, and clonidine do not clinically improve severity of OSA. The effects of antihypertensive agents on sleep apnea are inconsistent and are likely not clinically significant.

Modafinil (Provigil) is a wake-promoting medication and is FDA approved to improve wakefulness in patients who have residual daytime sleepiness while treated with PAP. Initiation of wake-promoting medications should only be attempted in patients who are using optimal PAP therapy to alleviate sleep-disordered breathing and are free of cardiovascular disease. In patients with concurrent rhinitis, nasal steroids are recommended for use along with PAP therapy.
Individuals with sleep apnea should be evaluated after 1 to 3 months of treatment for improvement in alertness and daytime symptoms (improvement in memory and decreased irritability) and weight reduction. Individuals experiencing symptoms (e.g., daytime sleepiness, snoring, loss of blood pressure control) despite PAP therapy should have PSG repeated. Symptoms can recur if patients gain weight, requiring a higher pressure setting. Conversely, PAP pressure settings can be decreased if weight loss is achieved. Patient adherence to PAP therapy can be monitored by assessing the built-in compliance meter that measures the hours used at effective pressure.

**CENTRAL SLEEP APNEA**

CSA causes fragmented sleep and consequent daytime somnolence. However, unlike OSA, arousals from sleep are not required to initiate airflow. During PSG, there is an absence of airflow out of the mouth and nose with no activation of the inspiratory muscles. The prevalence of CSA is not well established and is less than OSA. CSA can be idiopathic but more commonly is caused by underlying autonomic nervous system lesions (e.g., cervical cordotomy), neurologic diseases (e.g., poliomyelitis, encephalitis, and myasthenia gravis), high altitudes, and congestive heart failure. For these reasons, potential underlying causes for CSA should be evaluated and treated. For example, worsening CSA in heart failure patients can signal the need to optimize heart failure therapies.

A few medications have been studied in the setting of high altitude, heart failure, and idiopathic CSA, including acetazolamide, which induces a metabolic acidosis that stimulates respiratory drive, and theophylline, which improves severity of CSA but has no effect on clinical variables. PAP therapy with or without supplemental oxygen also improves CSA. However, due to the lack of randomized trials there is no consensus on if and how CSA should be routinely managed, particularly in the setting of heart failure.

**NARCOLEPSY**

Narcolepsy is a severely debilitating neurologic disease that affects between 0.03% and 0.06% of adult Americans. Despite the debilitating nature of the disease, it can be undiagnosed or misdiagnosed for years. It is equal or somewhat higher in men compared with women, and it has been noted in children and adolescents. However, it is commonly recognized in the second decade of life and increases in severity through the third and fourth decades. Individuals with narcolepsy complain of excessive daytime sleepiness, and in the sleep laboratory, individuals with narcolepsy exhibit impairment of both the onset and the offset of REM and NREM sleep and have arousals and disturbed sleep during the night.

Four characteristic symptoms differentiate narcolepsy from other sleep disorders and are known as the narcolepsy tetrad: excessive daytime sleepiness, cataplexy, hypnagogic hallucinations, and sleep paralysis. Cataplexy, a sudden bilateral loss of muscle tone of varying severity and duration without the loss of consciousness, occurs in 70% to 80% of people with narcolepsy. Patients can suffer subtle changes, such as jaw or head slumping, or severe weakness, such as knee buckling or collapsing to the ground. Cataplexy is often precipitated by situations characterized by high emotion (e.g., laughter, anger, excitement). Catalectic episodes can be brief, lasting seconds, or can last for several minutes. Sleep paralysis is an episodic loss of voluntary muscle tone that occurs when the individual is falling asleep or waking. Individuals are conscious but not able to move or speak. Hallucinations while falling asleep (i.e., hypnagogic) and on awakening (i.e., hypnopompic) are brief, dreamlike experiences that intrude into wakefulness. Nearly 70% of narcoleptics experience these hallucinations. Unfortunately, these symptoms sometimes lead to an incorrect diagnosis of mental illness. Cataplexy, sleep paralysis, and hypnagogic hallucinations can be caused by REM sleep disturbances.

The primary cause of narcolepsy is not known, and causes may include multiple external and internal factors. There can be a genetic component, as 3% of patients have a first-degree relative with the disorder. Onset of disease occurs in adolescence or adulthood, but not at birth, suggesting that environmental influences might play a role. Molecular studies of human leukocyte antigen (HLA) have found a high prevalence of the HLA-DR2 and HLA-DQ6/DQB1 haplotypes in narcoleptics. However, the HLA-DR2 haplotype is also common in the non-narcoleptic population and is not diagnostic. The hypocretin-orexin neurotransmitter system has been implicated and can play a central role in narcolepsy. Neurons containing hypocretin-orexin are found in the lateral hypothalamus and project to various parts of the brain that are thought to regulate sleep. In 75% of narcoleptic patients, hypocretin-orexin is undetectable in cerebrospinal fluid. Because narcoleptic patients have deficiencies in hypocretin-orexin–producing neurons, an autoimmune process may be responsible for the destruction of hypocretin-producing cells.

**TREATMENT**

**Narcolepsy**

Nonpharmacologic management of narcolepsy includes counseling the patient and family concerning the illness to alleviate misconceptions around the individual’s behavior. Good sleep hygiene should be encouraged as well as two or more scheduled daytime naps. Daytime naps lasting 15 minutes each can help the individual with narcolepsy stay refreshed for several hours.

Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness (EDS) and cataplexy. Drug therapy for narcolepsy is summarized in Table 81–4.

Modafinil, a racemic compound unrelated to psychostimulants, is a recognized standard treatment for EDS. Armodafinil is the active R-isomer of modafinil and is also FDA approved for treatment of EDS in narcolepsy. The precise mechanism of action of modafinil and armodafinil is not fully understood. Common adverse effects are usually mild and include headache, nausea,
nervousness, anxiety, and insomnia. The dose of modafinil is between 200 and 400 mg/day, and armodafinil doses are between 150 mg and 250 mg/day. Although both of these agents are effective in treating EDS, they lack efficacy for the treatment of cataplexy symptoms.\(^5^9\)

EDS can also be treated with stimulants to improve alertness and to increase daytime performance. Dextroamphetamine and methylphenidate also have FDA approval for the treatment of narcolepsy. Methamphetamine has also been used on an off-label basis. Methylphenidate and amphetamines have a fast onset of action and durations of 6 to 10 and 3 to 4 hours, respectively. The dose can range from 5 to 60 mg daily. Many clinicians prescribe both immediate-release and sustained-release stimulants to increase alertness throughout the day. Sustained-release stimulants are prescribed with scheduled administration times, and immediate release stimulants can be taken as needed when the patient requires alertness (e.g., driving, etc.).

Stimulants improve alertness, increase daytime performance, can elevate mood, and prevent sleep. Side effects can include insomnia, hypertension, palpitations, and irritability. Tolerance to long-term stimulant therapy can occur, necessitating dosing adjustments. Amphetamine use is associated with more likelihood of abuse and tolerance, especially when prescribed in high doses. Lisdexamfetamine is a new amphetamine prodrug rapidly absorbed and converted in the body to dextroamphetamine. Lisdexamfetamine has a longer duration of action and less risk of abuse since it is only active when taken orally.

The most effective treatments for cataplexy are TCAs, venlafaxine, and fluoxetine. The mechanism of antidepressants in relieving cataplexy, hypnagogic hallucinations, and sleep paralysis can be mediated through blockade of serotonin and norepinephrine reuptake in the locus coeruleus and raphe and subsequent suppression of REM sleep.\(^5^4\) Imipramine, protriptyline, clomipramine, fluoxetine, and nortriptyline are effective in approximately 80% of patients. Selegiline improves hypersomnolence and cataplexy through REM suppression and an increase in REM latency. Methylphenidate and amphetamines alone are usually ineffective for cataplexy.

Sodium oxybate (\(\gamma\)-hydroxybutyrate, Xyrem) improves symptoms of EDS and decreases episodes of sleep paralysis, cataplexy, and hypnagogic hallucinations. Nightly administration of sodium oxybate changes sleep architecture to resemble normal sleep. It increases slow-wave sleep, decreases nighttime awakenings, and increases REM efficiency.\(^5^9\) Sodium oxybate is available only as a liquid and is taken as two doses; one is taken at bedtime and the second dose is taken 2.5 to 4 hours later. Sodium oxybate is a potent sedative hypnotic and should not be used concomitantly with any other sedating medications. The most common side effects include nausea, somnolence, confusion, dizziness, and incontinence.

**CIRCADIAN RHYTHM DISORDERS**

The sleep–wake cycle is under the circadian control of oscillators and can be disrupted by misalignment between an individual’s biologic clock and external demands on the sleep cycle. Circadian rhythm sleep disorders usually present with either insomnia or hypersomnia, depending on the individual’s performance requirements. Two commonly occurring circadian rhythm sleep disorders are jet lag and shift work sleep problems.

#### JET LAG

Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Sleep disturbances typically last for 2 to 3 days but can last as long as 7 to 10 days if the time zone changes are greater than 8 hours. Compared with westward travel, eastward travel is associated with a longer duration of jet lag. Jet lag leads to increased incidence of gastrointestinal disturbances and a decrease in alertness and performance.

Treatment of jet lag includes nonpharmacologic approaches alone or in combination with drug therapy. Jet lag can be minimized in coast-to-coast travel in the United States if the duration is less than 7 days and the normal sleep–wake cycle is observed. For travel lasting longer than 7 days, jet lag severity can be lessened by 1- to 2-hour adjustments in sleep and wake times prior to departure to the destination time zone. Short-acting benzodiazepine receptor agonists or 0.5 to 5 mg melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.\(^5^6\)

#### SHIFT WORK SLEEP DISORDER

Shift workers comprise approximately 20% of the workforce.\(^5^7\) Night shift work causes a misalignment in the sleep–wake cycle and circadian rhythm that is associated with a decrease in alertness, performance, and quality of daytime sleep. More than 65% of workers on...
rotating shifts complain of insomnia, compared with only 20% who work one shift. Shift workers ultimately are at risk of developing shift work sleep disorder (SWSD). SWSD is a complaint of insomnia or excessive sleepiness that occurs because of working shifts during normal sleep time. Shift workers have a higher injury rate, divorce rate, occurrence of on-the-job sleepiness, and incidence of substance use. Shift workers may also be at increased risk of developing peptic ulcers, depression, breast cancer, and sleepiness-related accidents. Night shift workers are usually in a state of permanent circadian misalignment because of the tendency to revert to conventional sleep schedules on their days off. Treatment for shift work sleep problems includes optimizing sleep hygiene, extending daytime sleep by sleeping in the afternoon, scheduling a 2- to 3-hour nap on days off from work, or switching to a day shift job. Short-acting benzodiazepine receptor agonists can consolidate sleep during day sleep periods and reduce lost sleep time. Modafinil is FDA approved to improve wakefulness in patients with excessive daytime sleepiness associated with SWSD. Scheduled exposure to bright lights at night and darkness in the daytime improves adaptation to night work and daytime sleep. Melatonin has also been used successfully.

RESTLESS LEGS SYNDROME

Restless legs syndrome (RLS), or Ekborn syndrome, is characterized by paresthesias that are usually felt deep in the calf muscles but can also appear in the thighs and arms with the urge to keep limbs in motion. RLS occurs in both males and females, and it occurs more frequently in the elderly. It has been associated with chronic kidney disease, iron deficiency anemia, and pregnancy. Caffeine, stress, alcohol, and fatigue can worsen symptoms. Recent data suggest that RLS can be caused by iron deficiency in the substantia nigra. The diagnosis of RLS is based on patient- or partner-reported symptoms and specific diagnostic criteria. Criteria required to diagnose RLS include (1) an urge to move the limbs that is usually associated with uncomfortable and unpleasant sensations, (2) symptoms that begin or worsen during rest or inactivity, (3) symptoms that are exclusively present or worse in the evening or night, and (4) symptoms that are temporarily relieved by movement. The discomfort returns when the person tries to sleep, resulting in insomnia.

Dopamine agonists are effective for RLS and have replaced levodopa as first-line therapy. Ropinirole and pramipexole are FDA approved for RLS. Lower doses of dopamine agonists are used when treating RLS compared with Parkinson disease. Providers should caution patients that compulsive behaviors (e.g., gambling, shopping, eating, etc.) may emerge during therapy with dopamine agonists. Levodopa therapy is associated with a high incidence of symptom augmentation and, because of a short half-life, might not provide relief over the entire night. Augmentation is a worsening in symptom severity, increase in symptom distribution, or emergence of symptoms earlier in the evening. Sedative hypnotic agents can be effective in patients who have frequent awakenings from their RLS symptoms. Clonazepam at doses ranging from 0.5 mg to 2 mg has been most frequently studied; however, patients frequently experience carryover sedation because of its long duration of action. Shorter half-life sedative hypnotics (e.g., zolpidem, zaleplon, triazolam) can improve sleep and reduce daytime sleepiness without carryover sedation. Opiates such as methadone 5 to 20 mg, codeine 30 to 120 mg, and oxycodone 2.5 mg are very effective for patients with painful RLS. The potential for tolerance and dependence on opiate therapy should be considered. Gabapentin 300 to 900 mg near bedtime can also be considered for those with paresthetic or painful RLS symptoms. Iron studies should be completed in patients with RLS and iron supplementation initiated in those that are iron deficient. In patients with ferritin concentrations less than 50 to 75 mcg/L (ng/mL), iron supplementation improves RLS symptoms. Patients with RLS or periodic limb movements of sleep should be evaluated regularly to monitor for excessive daytime somnolence, tolerance, efficacy, and adverse effects of the medication.

PERIODIC LEG MOVEMENTS OF SLEEP

RLS patients commonly have periodic limb movements during sleep, while approximately one-third of patients with PLMS have RLS. PLMS are stereotypic, repetitive, periodic movements of the legs that occur during sleep every 20 to 40 seconds and last 10 minutes to several hours. The movements usually involve the big toe, but the ankle, knee, and hip can also flex. They can be terminated by a violent kick or other body movement. Often patients will be unaware of these movements and only recognize consequent insufficient sleep and morning leg cramps. A bed partner can describe PLMS. PLMS is diagnosed in the sleep laboratory using electromyogram recordings. Bursts of muscle activity lasting 0.5 to 5 seconds that recur at least 40 times within 8 hours of sleep are diagnostic.

PLMS can occur with RLS or alone because of systemic disease (e.g., renal failure) or drug therapy. TCAs, SSRIs, dopaminergic antagonists, xanthines, nicotine, alcohol, and caffeine can all worsen PLMS. The treatment approach for PLMS is similar to that of RLS. If PLMS do not cause disruptions for the patient or bed partner or daytime symptoms, they might not require treatment. Symptomatic or problematic PLMS should be treated with dopaminergic medications to suppress limb movements or sedative hypnotics to reduce awakenings and consolidate sleep.

PARASOMNIAS

Parasomnias are abnormal behavior or physiologic events that either occur during sleep or are exaggerated by sleep. Many of these disorders are considered to be disorders of partial arousal from various sleep stages. Parasomnias can be categorized as disorders of arousal (sleepwalking, sleep terrors), sleep–wake transition disorders (sleep talking), rhythmic movement disorder, REM parasomnias (REM-behavior disorder, nightmares), and miscellaneous parasomnias (enuresis, bruxism). Sleepwalking, sleep terrors, and sleep talking predominantly occur during NREM sleep, whereas others (REM-behavior disorder) occur during REM sleep.

Sleepwalking and sleep terrors are found normally in children between the ages of 4 and 12 years and usually resolve in adolescence. These disorders are associated with psychopathology only if they persist into adulthood. Sleep terrors can begin in adults between the ages of 20 and 30 years. Onset of sleepwalking in adults without a childhood history of sleepwalking should prompt a search for a neurologic or substance-use condition. Sleepwalking and sleep terror disorder involve intrusions of wakefulness into NREM sleep during the first third of the night. In sleepwalking, individuals become ambulatory, are difficult to awaken, and are amnestic for the event. Sleep terrors involve intense fear and autonomic arousal. Individuals are difficult to awaken, inconsolable, and amnestic for the event. Patients with REM-behavior disorder act out their dreams, often in a violent manner, and are at risk for injury.

Treatment of sleepwalking involves protecting the individual from harm by putting safety latches on doors and windows, removing hazardous objects from bedrooms, and covering glass doors with heavy curtains. In adult patients, benzodiazepines, SSRIs, or TCAs can be beneficial therapies for sleepwalking or other
NREM disorders of arousal. Benzodiazepines can also be helpful in curtailing sleep terrors in adults. Nightmares are anxiety-provoking dreams characterized by vivid recall. Treatment is directed at reducing stress, anxiety, and sleep deprivation. In extreme cases, low-dose benzodiazepines can be indicated. Clonazepam is the treatment of choice for REM behavior disorder. Melatonin (3–12 mg at bedtime) can also be an effective therapy for REM behavior disorder.

PHARMACOECONOMIC CONSIDERATIONS

Despite the prevalence of sleep disorders, most cases go undiagnosed and untreated. In the United States, the direct and indirect costs of insomnia alone add over $100 billion to the national health care bill each year. Improvements in recognition and treatment can decrease the economic burden and prevent progression to both medical and psychiatric disorders. Quality of life can be improved by appropriate treatment. For example, treatment of OSA with PAP improves the number of years of good health by 5.5 quality-adjusted life years. Hypnotic therapy has also been found to markedly improve both the disorder and quality of life in shift workers.

CONCLUSIONS

Disturbances of sleep affect approximately one third of the population. Patients with sleep disorders should be accurately identified and diagnosed. Patients can have one or more concomitant sleep disorders. Unrecognized and poorly treated sleep disorders can worsen severity of and ability to effectively treat underlying systemic diseases. Effective management of sleep disorders involves combined nonpharmacologic and pharmacologic treatment.

REFERENCES

Persons diagnosed with Down syndrome can be at increased risk for medical and psychiatric comorbidities.

Develop treatment plans for persons with autism to increase social interactions, improve verbal and nonverbal communication, and minimize the occurrence or impact of ritualistic, repetitive behaviors and other related mood and behavioral problems (e.g., overactivity, irritability, self-injury).

Differentiate between purported treatments for autism and effective treatments supported by evidence-based pharmacotherapy principles.

Develop a structured teaching approach focusing on increasing social communication and integration with peers in persons with autism.

Develop a psychopharmacologic treatment plan including monitoring of objective and measurable medication-responsive target behaviors and assessment of potential adverse effects.

Differentiate between the four stages of Rett syndrome associated with developmental regression.

Intellectual disabilities (ID) can be identified in childhood or adolescence. Current criteria for a diagnosis are based on deficiencies in intellectual and adaptive functioning with an onset prior to 18 years of age. This diagnosis is made regardless of the presence or absence of concomitant medical or psychiatric disorders. In the case of mild ID, deficiencies may not be initially apparent. Problems can be noted when the chronologic age of the child and the developmental milestones achieved by peers with similar backgrounds, cultures, and socioeconomic and psychosocial settings differ significantly. These gaps widen as the individual ages.

Adaptive functioning deficits pose a number of challenges in treating those with an ID. This population can be 4 to 5 times more likely to experience mental health problems compared with the general population. Until recently, little attention was given to this population and the need to evaluate them for psychiatric illnesses, leading to under-recognition of psychopathology. This oversight is a function of several factors, including limited population-specific training for clinicians and a general lack of clinical experience with patients with ID during training. Additional barriers are individual deficits in expressive and receptive language, a lack of mental health screening initiatives, and limited diagnostic testing instruments specific to this population.

Those with ID often have few social interactions and limited integration into the community. Stimulation and interaction with peers typically shapes behaviors in the general population. A different set of coping skills can develop in their absence. Self-talk is an example of a coping mechanism that can be misinterpreted for psychosis. Another potential problem for the clinician assessing persons with an ID is a significant gap between receptive and expressive language skills. If not readily recognized, intellectual capabilities can be overestimated, expectations falsely elevated, and coping skills can be inadequate, leading to anxiety-induced decompensation.

Diabetes mellitus (DM) is a group of metabolic disorders of fat, carbohydrate, and protein metabolism that results from defects in insulin secretion, insulin action (sensitivity), or both. The incidence of type 2 DM is increasing. This has been attributed in part to a Western-style diet, increasing obesity, sedentary lifestyle, and an increasing minority population. The two major classifications of DM are type 1 (insulin deficient) and type 2 (combined insulin resistance and relative deficiency in insulin secretion). They differ in clinical presentation, onset, etiology, and progression of disease. Both are associated with microvascular and macrovascular disease complications.

Diagnosis of diabetes is made by four criteria: fasting plasma glucose \( \geq 126 \text{ mg/dL} \); a 2-hour value from a 75-g oral glucose tolerance test \( \geq 200 \text{ mg/dL} \); a casual plasma glucose level of \( \geq 200 \text{ mg/dL} \) with symptoms of diabetes; or a \( \text{HbA}_1c \geq 6.5\% \). The diagnosis should be confirmed by repeat testing if obvious hyperglycemia is not present.

Goals of therapy in DM are directed toward attaining normoglycemia (or appropriate glycemic control based on the patient's comorbidities), reducing the onset and progression of retinopathy, nephropathy, and neuropathy complications, intensive therapy for associated cardiovascular risk factors, and improving quality and quantity of life.

Metformin should be included in the therapy for all type 2 DM patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality, according to the United Kingdom Prospective Diabetes Study (UKPDS).

Intensive glycemic control is paramount for reduction of microvascular complications (neuropathy, retinopathy, and nephropathy) as evidenced by the Diabetes Control and Complications Trial (DCCT) in type 1 DM and the UKPDS in type 2 DM. The UKPDS also reported that control of hypertension in patients with diabetes will not only reduce the risk of retinopathy and nephropathy, but also reduce cardiovascular risk.

Short-term (3–5 years), intensive glycemic control does not lower the risk of macrovascular events as reported by the Action in Diabetes and Vascular Disease, Action to Control Cardiovascular Risk in Diabetes, and Veterans Administration Diabetes Trial trials. Microvascular event reduction may be sustained, and macrovascular events reduced by improved early glycemic control, as evidenced by the UKPDS and DCCT follow-up studies. Significant reductions in macrovascular risk may take 15 to 20 years. This sustained reduction in microvascular risk and new reduction in macrovascular risk has been coined metabolic memory.

Knowledge of the patient's quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations, and pharmacology of oral and injected antihyperglycemic agents are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.

Type 1 DM treatment necessitates insulin therapy. Currently, the basal-bolus insulin therapy or pump therapy in motivated individuals often leads to successful glycemic outcomes. Basal-bolus therapy includes a basal insulin for fasting and postabsorptive control, and rapid acting bolus insulin for mealtime coverage. Addition of mealtime pramlintide in patients with uncontrolled or erratic postprandial glucose may be warranted.

Type 2 DM treatment often necessitates use of multiple therapeutic agents (combination therapy), including oral and/or injected antihyperglycemics and insulin to obtain glycemic goals due to the persistent reduction in \( \beta \)-cell function over time.
Endocrinologic Disorders

SECTION 8

Insulin requirements. Type 1 DM accounts for 5% to 10% of all DM idiopathic is a nonimmune form of diabetes frequently seen or early adulthood, although some latent forms do occur. Type 1 DM is an autoimmune disorder developing in childhood as many as one-fourth of these patients being undiagnosed, and characterized by hyperglycemia. It is associated with abnormalities in/glucose tolerance, impaired fasting glucose, or HbA1c 5.7%–6.4% (see diagnosis of diabetes section); hypertension (≥140/90 mm Hg in adults); high-density lipoprotein (HDL) cholesterol ≤35 mg/dL and/or a triglyceride level ≥250 mg/dL; history of gestational diabetes mellitus (GDM) (see classification of diabetes section) or delivery of a baby weighing >9 pounds; history of vascular disease; presence of acanthosis nigricans; and polycystic ovary disease. The prevalence of type 2 DM increases with age, it is more common in women than in men in the United States, and varies widely among various racial and ethnic populations, being especially increased in some groups of Native Americans, Hispanic American, Asian American, African American, and Pacific Island people (Fig. 83–2). While the prevalence of type 2 DM increases with age (Fig. 83–2), the disorder is increasingly being recognized in adolescence.

Prevention strategies for type 1 DM have been unsuccessful. Prevention strategies for type 2 DM are established. Lifestyle changes, dietary restriction of fat, aerobic exercise for 30 minutes 5 times a week, and weight loss, form the backbone of successful prevention. No medication is currently FDA approved for prevention of diabetes, though several, including metformin, acarbose, pioglitazone, and rosiglitazone, have clinical trials demonstrating a delay of diabetes onset.

Patient education and ability to demonstrate self-care and adherence to therapeutic lifestyle and pharmacologic interventions are crucial to successful outcomes. Multidisciplinary teams of healthcare professionals including physicians (primary care, endocrinologists, ophthalmologists, and vascular surgeons), podiatrists, dietitians, nurses, pharmacists, social workers, behavioral health specialists, and certified diabetes educators are needed, as appropriate, to optimize these outcomes in persons with diabetes mellitus.

Diabetes mellitus (DM) is a group of metabolic disorders characterized by hyperglycemia. It is associated with abnormalities in carbohydrate, fat, and protein metabolism and results in chronic complications including microvascular, macrovascular, and neuropathic disorders. Nearly 24 million Americans have DM, with as many as one-fourth of these patients being undiagnosed, and an additional 57 million potentially having pre-diabetes. The economic burden of DM approximated $174 billion in 2007, including direct medical and treatment costs as well as indirect costs attributed to disability and mortality. DM is the leading cause of blindness in adults aged 20 to 74 years, and the leading contributor to development of endstage renal disease. It also accounts for approximately 71,000 lower extremity amputations annually. Finally, a cardiovascular event is responsible for two-thirds of deaths in individuals with type 2 DM.

Optimal management of the patient with DM will reduce or prevent complications, and improve quality of life. Research and drug development efforts over the past several decades have provided valuable information that applies directly to improving outcomes in patients with DM and have expanded the therapeutic armamentarium. Additionally, interventions in an attempt to prevent complications and the onset of diabetes have been reported for type 1 and 2 DM.

EPIDEMIOLOGY

Type 1 DM is an autoimmune disorder developing in childhood or early adulthood, although some latent forms do occur. Type 1 DM idiopathic is a nonimmune form of diabetes frequently seen in minorities, especially Africans and Asians, with intermittent insulin requirements. Type 1 DM accounts for 5% to 10% of all cases of DM and is likely initiated by the exposure of a genetically susceptible individual to an environmental agent. Candidate genes and environmental factors are reportedly prevalent in the general population, but development of β-cell autoimmunity occurs in less than 10% of the genetically susceptible population and progresses to type 1 DM in less than 1% of the population. The prevalence of β-cell autoimmunity appears proportional to the incidence of type 1 DM in various populations. For instance, the countries of Sweden, Sardinia, and Finland have the highest prevalence of islet cell antibody (3%–4.5%) and are associated with the highest incidence of type 1 DM; 22 to 35 per 100,000. The prevalence of type 1 DM has been increasing over the last hundred years, but the cause of the increase is not fully understood.

Markers of autoimmunity have been detected in 14% to 33% of persons with type 2 DM in some populations and manifest with early failure of oral agents and insulin dependence. This type of DM has also been referred to as latent autoimmune diabetes in adults (LADA).

Maturity onset diabetes of youth (MODY), which can be due to one of at least six genetic defects, and endocrine disorders such as acromegaly and Cushing syndrome, can be secondary causes of DM. These unusual etiologies, however, only account for 1% to 2% of the total cases of type 2 DM. See the section on other forms of diabetes mellitus later in this chapter for further discussion.

The prevalence of type 2 DM is increasing. Type 2 DM accounts for as much as 90% of all cases of DM, and overall the prevalence of type 2 DM in the United States is about 10.7% in persons age 20 or older. Additionally, there is likely one person undiagnosed for every four persons currently diagnosed with the disease. Multiple risk factors for the development of type 2 DM have been identified, including family history (i.e., parents or siblings with diabetes); obesity (i.e., ≥20% over ideal body weight, or body mass index [BMI] ≥25 kg/m2); habitual physical inactivity; race or ethnicity (see list below); previously identified impaired glucose tolerance, impaired fasting glucose, or HbA1c 5.7%–6.4% (see diagnosis of diabetes section); hypertension (≥140/90 mm Hg in adults); high-density lipoprotein (HDL) cholesterol ≤35 mg/dL and/or a triglyceride level ≥250 mg/dL; history of gestational diabetes mellitus (GDM) (see classification of diabetes section) or delivery of a baby weighing >9 pounds; history of vascular disease; presence of acanthosis nigricans; and polycystic ovary disease. The prevalence of type 2 DM increases with age, it is more common in women than in men in the United States, and varies widely among various racial and ethnic populations, being especially increased in some groups of Native Americans, Hispanic American, Asian American, African American, and Pacific Island people (Fig. 83–1). While the prevalence of type 2 DM increases with age (Fig. 83–2), the disorder is increasingly being recognized in adolescence.

Diabetes Mellitus

CHAPTER 83

Gestational diabetes mellitus complicates roughly 7% of all pregnancies in the United States. Most women will return to normoglycemia postpartum, but 30% to 50% will develop type 2 DM or glucose intolerance later in life.

PATHOGENESIS, DIAGNOSIS, AND CLASSIFICATION

CLASSIFICATION OF DIABETES

Diabetes is a metabolic disorder characterized by resistance to the action of insulin, insufficient insulin secretion, or both. The clinical manifestation of these disorders is hyperglycemia. The vast majority of diabetic patients are classified into one of two broad categories: type 1 diabetes caused by an absolute deficiency of insulin, or type 2 diabetes defined by the presence of insulin resistance with an inadequate compensatory increase in insulin secretion. Women who develop diabetes due to the stress of pregnancy are classified as having gestational diabetes. Finally, uncommon types of diabetes caused by infections, drugs, endocrinopathies, pancreatic destruction, and known genetic defects are classified separately (Table 83–1).

Much of the rise in adolescent type 2 DM is related to an increase in adiposity and sedentary lifestyle, in addition to an inheritable predisposition. Most cases of type 2 DM do not have a well-known cause; therefore, it is uncertain whether it represents a few or many independent disorders manifesting as hyperglycemia.

Gestational diabetes mellitus is defined as glucose intolerance which is first recognized during pregnancy. Clinical detection is important, as therapy will reduce perinatal morbidity and mortality.

Other Specific Types of Diabetes

Genetic Defects  Maturity onset diabetes of youth is characterized by impaired insulin secretion in response to a glucose stimulus with minimal or no insulin resistance. Patients typically exhibit mild hyperglycemia at an early age, but diagnosis may be delayed, depending on the severity of presentation. The disease is inherited in an autosomal dominant pattern with at least six different loci identified to date (MODY 2 and 3 are most common). The production of mutant insulin molecules has been identified in a few families and results in mild glucose intolerance.

Several genetic mutations have been described in the insulin receptor and are associated with insulin resistance. Type A insulin resistance refers to the clinical syndrome of acanthosis nigricans, virilization in women, polycystic ovaries, and hyperinsulinemia. In contrast, type B insulin resistance is due to autoantibodies to the insulin receptor. Leprechaunism is a pediatric syndrome with specific facial features and severe insulin resistance due to a defect in the insulin-receptor gene. Lipodystrophic diabetes probably results from postreceptor defects in insulin signaling.

Screening

Type 1 Diabetes Mellitus

There is still a low prevalence of type 1 DM in the general population and due to the acuteness of symptoms in most individuals, screening for type 1 DM is not recommended. Screening for islet autoantibody status in high-risk family members may be appropriate, but is recommended to be done in the context of ongoing clinical trials for the prevention of type 1 DM.

Type 2 Diabetes Mellitus

Based on expert opinion, and not uniformly accepted by all guidance organizations, the American Diabetes Association (ADA) recommends screening for type 2 DM at any age in individuals with who are overweight (BMI ≥25 kg/m²) and have at least one other risk factor. The recommended screening test is the fasting plasma glucose, HbA1c, or 2-hour oral glucose tolerance test (OGTT). Adults without risk factors should be screened starting at age 45 years, as age itself is a risk factor for type 2 DM. The optimal time between screenings is not known. The index of suspicion for the presence of diabetes should guide the clinician.

Children and Adolescents

Despite a lack of clinical evidence to support widespread testing of children for type 2 DM, it is clear that more children and adolescents are developing type 2 DM. The ADA, by expert opinion, recommends that overweight (defined as BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal [50th percentile] for height) youths with at least two of the following risk factors: a family history of type 2 diabetes in first- and second-degree relatives; Native Americans, African Americans, Hispanic Americans, and Asians/South Pacific Islanders; those with signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, or small for gestational age birthweight); or maternal history of diabetes or gestational diabetes mellitus during the child’s gestation be screened. Screening should be done every 3 years starting at 10 years of age or at the onset of puberty if it occurs at a younger age.

Gestational Diabetes

Risk assessment for GDM should occur at the first prenatal visit. Women at high risk (positive family history, history of GDM or delivery of large-for-gestational–age infant, marked obesity, diagnosis of polycystic ovary syndrome, or member of a high-risk ethnic group) should be screened as soon as feasible. If the initial screening is negative they should undergo retesting at 24 to 28 weeks’ gestation, as should all other pregnant women with the possible exception of low-risk primigravidas. Evaluation for GDM can be done in one of two ways. The one-step approach involves a 3-hour, 100 g-OGTT and may be cost-effective in high-risk patient populations. The two-step approach uses a screening test to measure plasma or serum glucose concentration 1 hour after a 50-g oral glucose load (glucose challenge test [GCT]), followed by a diagnostic 3-hour OGTT on the subset of women exceeding a glucose threshold of either ≥140 mg/dL (80% sensitive) or ≥130 mg/dL (90% sensitive). The diagnosis of GDM is based on the 100-g OGTT and at least two measured glucose values meeting or exceeding criteria. Criteria for diagnosis of GDM based on the OGTT are summarized in Table 83–2.

Two or more values must be met or exceeded for a diagnosis of diabetes to be made. The test should be done in the morning after an 8- to 14-hour fast.
### Criteria for the Diagnosis of Diabetes Mellitus

1. **HbA₁c ≥ 6.5%**: The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay.

2. **Fasting plasma glucose ≥ 126 mg/dL (7.0 mmol/L)**. Fasting is defined as no caloric intake for at least 8 hours.

3. **2-hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L)** during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

4. **In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis**, a random plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L).

In the absence of unequivocal hyperglycemia, criteria 1 to 3 should be confirmed by repeat testing.

### Figure 83-3

Prevalence of retinopathy by deciles of the distribution of fasting plasma glucose (FPG), 2-hour postprandial glucose (2-h PG), and hemoglobin A₁c (HbA₁c) in (A) Pima Indians, (B) Egyptians, and (C) in 40- to 74-year old participants in National Health and Nutrition Examination Survey (NHANES) III.

The x-axis labels indicate the lower limit of each decile group. Note that these deciles and the prevalence rates of retinopathy differ considerably among the studies, especially the Egyptian study, in which diabetic subjects were oversampled. Retinopathy was ascertained by different methods in each study; therefore, the absolute prevalence rates are not comparable between studies, but their relationships with FPG, 2-h PG, and HbA₁c are very similar within each population.
HbA\textsubscript{lc} ≥6.5% has been newly added as a fourth diagnostic criterion for diabetes mellitus. The HbA\textsubscript{lc} was not recommended in the past due to many nonstandardized assays. Most laboratories now use a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay, which allows for cross-application of their results. If standardized, the HbA\textsubscript{lc} is logical for the diagnosis of diabetes as it measures glycemic exposure over the past 2 to 3 months, in contrast to a single-day, single-point glucose evaluation. In addition, patients do not have to be fasting. A HbA\textsubscript{lc} of 6.0% to 6.4% denotes a 10-fold increase in risk of diabetes, yet does not consistently identify patients with impaired fasting glucose or impaired glucose tolerance. In addition, there are slight race differences in normal HbA\textsubscript{lc} levels, so 6.5% was chosen to minimize these limitations. The ADA continues to recommend three other glucose criteria for the diagnosis of diabetes mellitus in nonpregnant adults (Table 83–3). It should be noted that a continuum of risk exists as glycemia increases, and sound clinical judgment as to the future risk of diabetes in the context of HbA\textsubscript{lc} and plasma glucose levels should be applied. If the patient has obvious hyperglycemia and diabetes, reconfirmation is no longer needed.

In addition, as shown in Table 83–4, the ADA added a HbA\textsubscript{lc} value of 5.7% to 6.4% to define an increased risk for diabetes. The HbA\textsubscript{lc} lower limit of 5.7% was chosen due to its good specificity, though it has a low sensitivity, to identify patients at increased risk for diabetes. Impaired fasting glucose (IFG) continues to be defined as a plasma glucose of at least 100 mg/dL (5.6 mmol/L) but less than 126 mg/dL (7.0 mmol/L). Impaired glucose tolerance (IGT), is defined as a 2-hour glucose value ≥140 mg/dL (7.8 mmol/L), but less than 200 mg/dL (11.1 mmol/L) during a 75-g OGTT.

Serial measurements, at clinician-defined intervals, can help to identify patients moving toward diabetes, and those who are stable. Patients who have even minor increases in glucose or HbA\textsubscript{lc} values over time should be followed closely. Pathophysiologically, the fasting and postprandial glucose levels do not measure the same physiologic processes. The fasting glucose reflects hepatic glucose production, which is mainly determined by the insulin secretory capacity and glucagon released by the pancreas. The postprandial glucose reflects uptake of glucose in peripheral tissues (muscle and fat) and depends on insulin sensitivity of these tissues. Also, the HbA\textsubscript{lc} measurement can be affected by several hemoglobinopathies, which necessitates the use of one of the plasma glucose criterion in these individuals.

### PATHOGENESIS

#### Type 1 Diabetes Mellitus

Type 1 DM is characterized by an absolute deficiency of pancreatic β-cell function. Most often this is the result of an immune-mediated destruction of pancreatic β cells, but rare unknown or idiopathic processes may contribute. In immune mediated, a potential disruption of the T-helper 1/T-helper 2 balance may lead to higher T-helper 1 activity, with subsequent activation of the immune system and eventual destruction of pancreatic β cell.

What is evident are four main features: (1) a long preclinical period marked by the presence of immune markers when β-cell destruction is thought to occur; (2) hyperglycemia when 80% to 90% of β cells are destroyed; (3) transient remission (the so-called “honeymoon” phase); and (4) established disease with associated risks for complications and death. Unknown is whether there is one or more inciting factors (e.g., cow’s milk, or viral, dietary, or other environmental exposure) that initiate the autoimmune process (Fig. 83–4). Vitamin D deficiency has been observed to be more prevalent in patients who develop type 1 DM, and potential mechanisms, including a role of vitamin D in reduction of interferon-γ and several interleukins, have been proposed. Observational data supports a potential role, but further study is needed.\(^{17}\)

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β-cell antigens. The most commonly detected antibody associated with type 1 DM is the islet cell antibody. The test for islet cell antibody, however, is difficult to standardize across laboratories. Other more readily measured circulating antibodies include insulin autoantibodies, antibodies directed against glutamic acid decarboxylase, insulin antibodies against islet tyrosine phosphatase, and several others. More than 90% of newly diagnosed persons with type 1 DM have one or another of these antibodies, as will 3.5% to 4% of unaffected first-degree relatives. Preclinical β-cell autoimmunity precedes the diagnosis of type 1 DM by up to 9 to 13 years. Autoimmunity may remit in some perhaps less-susceptible persons, or can progress to β-cell failure in others. These antibodies

\(^a\)Diagnosis to be confirmed if not unequivocal hyperglycemia (see Table 83–3).
are generally considered markers of disease rather than mediators of \( \beta \)-cell destruction. They have been used to identify individuals at risk for type 1 DM in evaluating disease prevention strategies. Other nonpancreatic autoimmune disorders are associated with type 1 DM, most commonly Hashimoto thyroiditis, but the extent of organ involvement can range from no other organs to polyglandular failure.\(^{18}\)

There are strong genetic linkages to the DQA and B genes and certain human leukocyte antigens (HLAs) may be predisposing (DR3 and DR4) or protective (DRB1*04008-DQB1*0302 and DRB1*0411-DQB1*0302) on chromosome 6.\(^{18}\) Other candidate gene regions have been identified on several other chromosomes as well. Because twin studies do not show 100% concordance, environmental factors such as infectious agents, chemical agents, and dietary agents are likely contributing factors in the expression of the disease.

Destruction of pancreatic \( \beta \)-cell function causes hyperglycemia due to an absolute deficiency of both insulin and amylin.\(^{19}\) Insulin lowers blood glucose by a variety of mechanisms, including stimulation of tissue glucose uptake, suppression of glucose production by the liver, and suppression of free fatty acid (FFA) release from fat cells.\(^{20}\) The suppression of free fatty acids plays an important role in glucose homeostasis. Increased levels of free fatty acids inhibit the uptake of glucose by muscle and stimulate hepatic gluconeogenesis.\(^{21}\) Amylin, a glucoregulatory peptide hormone cosecreted with insulin, plays a role in lowering blood glucose by slowing gastric emptying, suppressing glucagon output from pancreatic alpha cells, and increasing satiety.\(^{22}\) In type 1 DM, amylin production, due to \( \beta \)-cell destruction, is very low.

**Type 2 Diabetes Mellitus**

**Normal Insulin Action** In the fasting state 75% of total body glucose disposal takes place in non–insulin-dependent tissues: the brain and splanchnic tissues (liver and gastrointestinal tissues).\(^{23}\) In fact, brain glucose uptake occurs at the same rate during fed and fasting periods and is not altered in type 2 diabetes.

The remaining 25% of glucose metabolism takes place in muscle, which is dependent on insulin.\(^{24}\) In the fasting state approximately 85% of glucose production is derived from the liver, and the remaining amount is produced by the kidney.\(^{24}\) Glucagon, produced by pancreatic \( \alpha \) cells, is secreted in the fasting state to oppose the action of insulin and stimulate hepatic glucose production. Thus, glucagon prevents hypoglycemia or restores normoglycemia if hypoglycemia has occurred.\(^{25}\) In the fed state, carbohydrate ingestion increases the plasma glucose concentration and stimulates insulin release from the pancreatic \( \beta \) cells. The resultant hyperinsulinemia (1) suppresses hepatic glucose production and (2) stimulates glucose uptake by peripheral tissues.\(^{24}\) The majority (\( \approx 80\% – 85\% \)) of glucose that is taken up by peripheral tissues is disposed of in muscle, with only a small amount (\( \approx 4\% – 5\% \)) being metabolized by adipocytes. In the fed state, glucagon is suppressed.

Although fat tissue is responsible for only a small amount of total body glucose disposal, it plays a very important role in the maintenance of total body glucose homeostasis. Small increments in the plasma insulin concentration exert a potent antilipolytic effect, leading to a marked reduction in the plasma FFA level. The resultant hyperinsulinemia (1) suppresses hepatic glucose production and (2) stimulates glucose uptake by peripheral tissues.\(^{24}\) The majority (\( \approx 80\% – 85\% \)) of glucose that is taken up by peripheral tissues is disposed of in muscle, with only a small amount (\( \approx 4\% – 5\% \)) being metabolized by adipocytes. at a value that is 2- to 2.5-fold greater than in normal weight nondiabetic controls. When the fasting plasma glucose concentration exceeds 140 mg/dL, the β cell is unable to maintain its elevated rate of insulin secretion and the fasting insulin concentration declines precipitously. This decrease in fasting insulin leads to an increase in hepatic glucose production overnight, which results in an elevated fasting plasma glucose concentration.

In the type 2 diabetic patient, decreased postprandial insulin secretion is due to both impaired pancreatic β cell function and a reduced stimulus for insulin secretion from gut hormones. The role gut hormones play in insulin secretion is best shown by comparing the insulin response to an oral glucose load versus an isoglycemic intravenous glucose infusion. In nondiabetic control individuals 73% more insulin is released in response to an oral glucose load compared to reproducing the oral glucose load’s plasma glucose curve by giving intravenous glucose (Fig. 83–7, left panel). This increased insulin secretion in response to an oral glucose stimulus is referred to as “the incretin effect” and suggests that gut-derived hormones when stimulated by glucose lead to an increase in pancreatic insulin secretion. In type 2 diabetic patients, this “incretin effect” is blunted with the increase in insulin secretion only being 50% of that seen in nondiabetic control individuals (Fig. 83–7). It is now known that two hormones, glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotheptin polypeptide (GIP), are responsible for over 90% of the increased insulin secretion seen in response to an oral glucose load. Patients with type 2 diabetes remain sensitive to GLP-1 while they are often resistant to GIP.

GLP-1 is secreted from the L-cells in the distal intestinal mucosa in response to mixed meals. Since GLP-1 levels rise within minutes of food ingestion neural signals initiated by food entry in the proximal gastrointestinal tract must simulate GLP-1 secretion. The insulinotheptin action of GLP-1 is glucose dependent, and for GLP-1 to enhance insulin secretion, glucose concentrations must be higher than 90 mg/dL. In addition to stimulating insulin secretion, GLP-1 suppresses glucagon secretion, slows gastric emptying, and reduces food intake by increasing satiety. The effects of GLP-1 combine to limit postprandial glucose excursions. GIP is secreted by K-cells in the intestine and, like GLP, increases insulin secretion. However, GIP has no effect on glucagon secretion, gastric motility, or satiety. The half-life of GLP-1 and GIP are short (<10 minutes). Both hormones are rapidly inactivated by removal of two N-terminal amino acids by the enzyme, dipeptidyl peptidase 4 (DPP-4). GLP-1 levels appear to decrease as glucose values increase from normal to type 2 DM.

Site of Insulin Resistance in Type 2 Diabetes

Liver In type 2 diabetic subjects with mild to moderate fasting hyperglycemia (140–200 mg/dL, 7.8–11 mmol/L), basal hepatic glucose production is increased by ~0.5 mg/kg/min. Consequently, during the overnight sleeping hours the liver of an 80-kg diabetic individual with modest fasting hyperglycemia adds an additional 35 g of glucose to the systemic circulation. This increase in fasting hepatic glucose production is the cause of fasting hyperglycemia.

Following glucose ingestion, insulin is secreted into the portal vein and carried to the liver, where it suppresses glucagon secretion and reduces hepatic glucose output. Type 2 diabetic patients fail to suppress glucagon in response to a meal and may even have a paradoxical rise in glucagon levels. Thus, hepatic insulin resistance and hyperglucagonemia result in continued production of glucose by the liver. Therefore, type 2 diabetic patients have two sources of glucose in the postprandial state, one from the diet and one from continued glucose production from the liver. These sources of glucose in combination with a shortened gastric emptying time may result in marked hyperglycemia.

Peripheral (Muscle) Muscle is the major site of glucose disposal in man, and approximately 80% of total body glucose uptake occurs in skeletal muscle. In response to a physiologic increase in plasma insulin concentration, muscle glucose uptake increases linearly, reaching a plateau value of 10 mg/kg/min. In contrast, in lean type 2 diabetic subjects, the onset of insulin action is delayed for ~40 minutes, and the ability of insulin to stimulate leg glucose uptake is reduced by 50%. Impaired insulin signaling is a well established abnormality, with notable impairments at almost every step of activation due to insulin resistance, lipo- and glucotoxicity. The compensatory hyperinsulinemia required to overcome impaired insulin signaling (insulin resistance) can activate an alternative pathway through MAP kinase, which may be involved in atherosclerosis. Mitochondrial dysfunction may also play a role in muscle insulin resistance. Mitochondrial function and density appear to be lower in some studies of type 2 DM. This may result in less energy expenditure and an increased risk of dysfunction with high-fat diets.

Peripheral (Adipocyte) In obese nondiabetic and diabetic humans, basal plasma FFA levels are increased and fail to suppress normally after glucose ingestion. FFAs are stored as triglycerides in adipocytes and serve as an important energy source during conditions of fasting. Insulin is a potent inhibitor of lipolysis, and restrains the release of FFAs from the adipocyte by inhibiting the hormone-sensitive lipase enzyme. It is now recognized that chronically elevated plasma FFA concentrations can lead to insulin resistance in muscle and liver, and impair insulin secretion. In addition to FFAs that circulate in plasma in increased amounts, type 2 diabetic and obese nondiabetic individuals have increased stores of triglycerides in muscle and liver, and the increased fat content correlates closely with the presence of insulin resistance in these tissues.

**FIGURE 83-7.** The loss of the incretin effect in type 2 diabetes mellitus. The plasma insulin responses to oral and intravenous glucose in nondiabetic subjects (left), compared with patients with diabetes (right). (Adapted from Nauck M, Stockmann F, Ebert R, Creutzfeldt W. Reduced Incretin Effect in Type 2 (non-insulin dependent) diabetes. Diabetologia 1986;29:46–52.)
In summary, insulin resistance involving both muscle and liver is a characteristic feature of glucose intolerance in type 2 diabetic individuals. In the basal state, the liver represents a major site of insulin resistance, and this is reflected by overproduction of glucose. This accelerated rate of hepatic glucose output is the primary determinant of the elevated fasting plasma glucose concentration in type 2 diabetic individuals. In the fed state, both decreased muscle glucose uptake and impaired suppression of hepatic glucose production contribute to the insulin resistance. In obese individuals and in the majority (>80%) of type 2 diabetic subjects, there is an expanded fat cell mass and the adipocytes are resistant to the antilipolytic effects of insulin. Most obese and diabetic individuals are characterized by expanded visceral adiposity, discussed in detail later in the chapter, which is especially refractory to insulin effects and results in a high lipolytic rate. Not surprisingly, both type 2 diabetes and obesity are characterized by an elevation in the mean 24-hour plasma FFA concentration. Elevated plasma FFA levels, as well as increased triglyceride/fatty acyl CoA content in muscle, liver, and β cells, lead to the development of muscle/hepatic insulin resistance and impaired insulin secretion.

Cellular Mechanisms of Insulin Resistance

Insulin resistance and the components of the insulin resistance syndrome are described below.

**Obesity and Insulin Resistance**  Weight gain leads to insulin resistance, and obese nondiabetic individuals have the same degree of insulin resistance as lean type 2 diabetic patients. In 1,146 non-diabetic, normotensive individuals, a progressive loss of insulin sensitivity when the BMI increased from 18 kg/m² to 38 kg/m² was documented. The increase in insulin resistance with weight gain is directly related to the amount of visceral adipose tissue. Subsets of obese, but metabolically normal patients do exist, as well as nonobese, but metabolically abnormal patients, so broad categorization of risk for a patient needs to be confirmed by further examination.

The term *visceral adipose tissue* (VAT) refers to fat cells located within the abdominal cavity and includes omental, mesenteric, retroperitoneal, and periphenic adipose tissue. VAT has been shown to correlate with insulin resistance and explain much of the variation in insulin resistance seen in a population of African Americans. Visceral adipose tissue represents 20% of fat in men and 6% of fat in women. This fat tissue has been shown to have a higher rate of lipolysis than subcutaneous fat, resulting in an increase in FFA production. These fatty acids are released into the portal circulation and drain into the liver, where they stimulate the production of very-low-density lipoproteins and decrease insulin sensitivity in peripheral tissues. VAT also produces a number of cytokines, such as TNF-α, interleukin 6, and resistin, which contribute to insulin resistance. These factors drain into the portal circulation and reduce insulin sensitivity in peripheral tissues.

The fat cell also has the capability of producing at least one hormone that improves insulin sensitivity: adiponectin. This factor is made in decreasing amounts as an individual becomes more obese. In animal models, adiponectin decreases hepatic glucose production and increases fatty acid oxidation in muscle.

**The Metabolic Syndrome**  The association of insulin resistance with a clustering of cardiovascular risk factors including hyperinsulinemia, hypertension, abdominal obesity, dyslipidemia, and coagulation abnormalities has been referred to by a variety of names including “insulin resistance syndrome,” “metabolic syndrome,” “dysmetabolic syndrome,” and “the deadly quartet,” to name a few. Since the description of the “insulin resistance syndrome” by Reaven in 1988, the number of associated factors has continued to grow. Metabolic syndrome is a risk indicator, but not an absolute risk indicator, because it does not specifically account for all risk factors, such as age, sex, low-density lipoprotein cholesterol levels, or directly measure hypercoagulability of the proinflammatory condition. Patients with metabolic syndrome do have a higher risk for cardiovascular disease (CVD), and at least a 5-fold increase in their risk of type 2 DM.

The most recent definition of metabolic syndrome was adopted by multiple organizations in 2009 (Table 83–5). Central obesity continues to be recognized as an important causative factor, but is no longer considered a prerequisite to having metabolic syndrome. Central obesity can be easily assessed using waist circumference, which is a good surrogate marker for VAT. It is imperative to measure the waist circumference correctly (just above hip bones and just below umbilicus, tape measure should be taught, but not tight), for accurate assessment. Ethnic group specific cut-points for waist circumference are pragmatic estimates taken from various data sources. As more complete data becomes available these values may be modified. Table 83–5 lists the ethnic specific values for waist circumference.

**Prevalence.** Regardless of the definition used, large numbers of adults in the United States have metabolic syndrome. The National Health and Nutrition Examination Survey (NHANES) 1999–2002 is the most scientifically rigorous sample of the U.S. population. A total of 3,601 men and women aged >20 years were included in the survey. Using the NCEP definition (Table 83–5), the prevalence of metabolic syndrome was 33.7% of men and 35.4% of women. In a sample of 4,060 predominantly European adults from South Australia, metabolic syndrome was present in 19.4% of men and 14.4% of women using the ATP III definition.

The impact of treating the clinical components of the metabolic syndrome in diabetes patients was demonstrated in the Steno-2 Study. In this prospective study, 63 patients with diabetes and microalbuminuria were randomized to the usual therapy group and 67 patients were treated intensively. Intensive therapy consisted of diet and exercise and pharmacologic intervention aimed at reducing hyperglycemia, hypertension, dyslipidemia, microalbuminuria, and increased coagulopathy (aspirin therapy). Treatment goals for intensive therapy included a blood pressure <130/80 mm Hg, HbA₁c <6.5%, total cholesterol <175 mg/dL, and triglycerides <150 mg/dL. All patients in the intensive treatment group were given an aspirin and treated with an angiotensin-converting enzyme (ACE) inhibitor. Patients in the intensively treated group showed a 53% relative risk reduction in cardiovascular disease and a 61% relative risk reduction in nephropathy. In this small study, the magnitude of this reduction is greater than has been demonstrated with individual interventions, stressing the importance of targeting all the components of the metabolic syndrome. The study design did not allow conclusions regarding which interventions had the most impact.

**CLINICAL PRESENTATION**

The clinical presentations of type 1 DM and type 2 DM are very different. Autoimmune type 1 DM can occur at any age. Approximately 75% will develop the disorder before age 20 years, but the remaining 25%, including relatives of index patients, develop the disease as adults. Individuals with type 1 DM are often thin and are prone to develop diabetic ketoacidosis if insulin is withheld, or under conditions of severe stress with an excess of insulin counterregulatory hormones. Twenty percent to 40% of patients with type 1 DM present with diabetic ketoacidosis after several days of polyuria, polydipsia, polyphagia, and weight loss.
Occasionally, type 1 DM patients are diagnosed without multiple symptoms or diabetic ketoacidosis when they have blood tests drawn for other reasons. Because newly diagnosed patients with type 1 DM often have a small amount of residual pancreatic $\beta$-cell function, they may enter a “honeymoon” phase, when their blood glucose concentrations are relatively easy to control and small amounts of insulin are needed. Once this residual insulin secretion wanes, the patients are completely insulin deficient and tend to have more labile glycemia. Not all type 1 DM patients have complete insulin deficiency, and a small residual amount of insulin secretion is seen in some patients. Patients with type 2 DM often present without symptoms, even though complications tell us that they may have been hyperglycemic for several years. Often these patients are diagnosed secondary to unrelated blood testing. Lethargy, polyuria, nocturia, and polydipsia can be seen at diagnosis in type 2 diabetes, but significant weight loss at diagnosis is less common. Clinically, diabetes mellitus is a spectrum of diseases ranging from absolute insulin deficiency to relative insulin deficiency, and patients can have normal to grossly abnormal insulin sensitivity. Classical clinical presentation characteristics should be used in conjunction with other definitive laboratory data to properly classify patients.

HDL-C indicates high-density lipoprotein cholesterol.

*a* It is recommended that the IDF cut points be used for non-Europeans and either the IDF or AHA/NHLBI cut points used for people of European origin until more data are available.

*b* The most commonly used drugs for elevated triglycerides and reduced HDL-C are fibrates and nicotinic acid. A patient taking 1 of these drugs can be presumed to have high triglycerides and low HDL-C. High-dose $\omega$-3 fatty acids presumes high triglycerides.

*c* Most patients with type 2 diabetes mellitus will have the metabolic syndrome by the proposed criteria.

Reproduced from Expert Panel on Detection. 124

GLYCEMIC GOAL SETTING AND HEMOGLOBIN A1C

Controlled clinical trials provide ample evidence that glycemic control is paramount in reducing microvascular complications in both type 1 DM and type 2 DM. Hemoglobin A1C (HbA1c) measurements are the gold standard for following long-term glycemic control for the previous 2 to 3 months. Hemoglobinopathies, anemia, red cell membrane defects, transfusions, and any patient where the red blood cell lifespan is substantially increased or decreased can affect HbA1c measurements. Minimization of problems, such as sickle cell trait, and assurance of standardized results can be accomplished by ensuring the test is performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay. Other strategies such as measurement of fructosamine, which measures glycated plasma proteins and correlates to glucose control over the last 2 to 3 weeks, may be necessary to assess diabetes control in patients with altered red blood cell lifespan, though the fructosamine is less standardized, and not correlated to risk of complications.

The A1C-Derived Average Glucose study correlated multiple HbA1c and glucose readings to term a new phrase, estimated average glucose (eAG) if abbreviated. The eAG better correlates with laboratory results. For example, a HbA1c of 6% or 7%, correlates with an average glucose of 126 mg/dL or 154 mg/dL, respectively, and online calculators and graphs are easily found.

Less stringent HbA1c goals (>7%) may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, at risk elderly, dementia, or in younger children. A HbA1c target of <7% is appropriate for others (Table 83–7), and lower values should be targeted if significant hypoglycemia, weight gain, and other adverse effects can be avoided. New glycemic control recommendations for different age groups of type 1 DM patients are now recommended, based on the risk of hypoglycemia, the relatively low risk of complications prior to puberty, and psychological and/or developmental issues (Table 83–7).

TREATMENT

Diabetes Mellitus

**DESIRED OUTCOME**

The primary goals of DM management are to reduce the risk for microvascular and macrovascular disease complications, to ameliorate symptoms, to reduce mortality, and to improve quality of life. Near-normal glycemia will reduce the risk for development of microvascular disease complications, but aggressive management of traditional cardiovascular risk factors (i.e., smoking cessation, treatment of dyslipidemia, intensive blood pressure control, and antiplatelet therapy) are needed to reduce the likelihood of development of macrovascular disease. Evidence-based guidelines, as published by the ADA, may help in the attainment of these goals (Table 83–6).

Hyperglycemia not only increases the risk for microvascular disease, but contributes to poor wound healing, compromises white blood cell function, and leads to classic symptoms of DM. Diabetic ketoacidosis and hyperosmolar hyperglycemic state are severe manifestations of poor diabetes control, almost always requiring hospitalization. Reducing the potential for microvascular complications is targeted at adherence to therapeutic lifestyle intervention (i.e., diet and exercise programs) and drug-therapy regimens, as well as at maintaining blood pressure as near normal as possible.

**GENERAL APPROACH TO TREATMENT**

Appropriate care requires goal setting for glycemia, blood pressure, and lipid levels, regular monitoring for complications, dietary and exercise modifications, medications, appropriate self-monitoring of blood glucose (SMBG), and laboratory assessment of the aforementioned parameters. Glucose control alone does not sufficiently reduce the risk of macrovascular complications in persons with DM.
concentration at any moment easily and relatively inexpensively. Frequent SMBG is necessary to achieve near-normal blood glucose concentrations and to assess for hypoglycemia and hyperglycemia, adjust prandial doses of insulin, and give corrective doses of insulin. This is particularly true in patients with type 1 DM, as most will be intensively managed with insulin. The more intense the pharmacological regimen is, the more intense the SMBG needs to be (four or more times daily in patients on multiple insulin injections or pump therapy whether type 1 or type 2 DM). The optimal frequency of SMBG for patients with type 2 DM on oral agents is unresolved. Frequency of monitoring in type 2 DM should be intensified with insulin. The more intense the insulin regimen, the more frequently SMBG should be performed. In adults, measure fasting lipid profile at least annually. Perform an annual urine albumin excretion in type 1 diabetes with duration ≥5 years. Type 2 DM from diagnosis. All patients should be screened for polyneuropathy at diagnosis and at least annually thereafter. A dilated eye exam should be performed within 5 years of diagnosis in type 1 DM, and shortly after diagnosis in type 2 DM, with follow-up every year, or every 2–3 years as recommended by an eye specialist.

### Glycemic goals
HbA1c goal for patients in general is <7%.

HbA1c goal should be individualized, with <7% if achieved without significant hypoglycemia or adverse effects. Less stringent HbA1c goal may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovacular complications or comorbidities, or in younger children.

### Treatment

#### Prevention of type 2 diabetes
Patients with IGT (A), IFG (E), or an A1C of 5.7–6.4% (E) should attempt weight loss (5%–10%), increasing physical activity.

Metformin may be considered in obese, <60-year-old patients at very high risk of diabetes, including “near” diabetes glucose or A1C, HTN, first-degree family history of diabetes.

#### Medical nutrition therapy
Weight loss is recommended for all insulin-resistant/obese or obese individuals. Either low-carbohydrate or low-fat calorie restricted diets may work.

In types 1 and 2 DM, intensive vs standard glucose control have not shown a significant reduction in CVD during randomized portions, but long-term follow-up of DCCT and UKPDS have shown targeting below A1C <7% may reduce long-term macrovascular disease.

Saturated fat should be <7% of total calories.

Glycemic index may give modest benefits over total carbohydrate intake.

#### Physical activity
150 minutes/week of moderate intensity exercise is recommended or 90 minutes of vigourous exercise/week.

Resistance training of large muscle groups should be 3 × week.

#### Blood pressure
Systolic blood pressure should be treated to <130 mm Hg.

Diastolic blood pressure should be treated to <80 mm Hg.

Initial drug therapy should be with an ACE inhibitor or ARB.

#### Nephropathy
Type 1 DM with any degree of albuminuria-ACE inhibitor.

Type 2 DM with microalbuminuria-ACE inhibitor or ARB.

Type 2 DM with macroalbuminuria-angiotensin receptor blocker.

#### Dyslipidemia
The primary goal is an LDL <100 mg/dL.

Statin therapy should be added to lifestyle, regardless of baseline lipid levels if patient has CVD, >40 years of age, and one other CVD risk factor.

In patients with overt CVD, using a statin to achieve a LDL <70 mg/dL is an optional goal.

Triglycerides should be lowered to <150 mg/dL.

Raising HDL to >40 mg/dL in men and >50 mg/dL in women.

Use aspirin (75–162 mg daily) for secondary cardioprotection.

Use aspirin (75–162 mg) for primary prevention in type 1 or 2 DM if the 10-year risk of CVD is >10%, or at least one additional risk factor is present.

Clopidogrel (75 mg/day) is appropriate for patients with CVD and documented aspirin allergy.

the palm, forearm, thigh, and stomach. These areas tend to have less nerve endings and may be more comfortable for a patient, but several cautions must be observed. Alternate site glucose readings will lag behind fingertip capillary blood, as the capillary flow and density is often less in the alternate testing sites when compared with the fingertip. Alternate site testing is discouraged in any situation where immediate action will be needed based on the glucose reading, such as testing for hypoglycemia or in others with the above issues noted.

### CLINICAL CONTROVERSY

SMBG improves glycemic control when insulin is used, but few well-conducted studies have shown significant glycemic reductions with increasing use of home blood glucose testing for type 2 DM patients not on insulin. The average HbA1c reduction with use of SMBG in type 2 DM patients not on insulin was 0.4%, though others have reported no glycemic improvement. Patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful glycemic improvement is likely to be effected, and thus the money spent on the strip is wasted.

Continuous glucose monitoring (CGM) may be useful in select patients. CGM measures interstitial glucose, which lags behind capillary SMBG, and the same cautions as alternate site testing should be followed. CGM can be useful in patients with frequent hypoglycemia or hypoglycemic unawareness, nocturnal hypoglycemia, for identification of fluctuating glucose patterns and/or previously unknown problems in patients with higher than expected HbA1c results. CGM still needs to be calibrated multiple times a day with SMBG readings to ensure accuracy, and a new sensor must be placed every 3 to 7 days. The ADA currently recommends that CGM can be considered in type 1 DM adults ≥25 years of age, and in others with the above issues noted.

### NONPHARMACOLOGIC THERAPY

#### Diet

Medical nutrition therapy is recommended for all persons with DM and along with activity, is a cornerstone of treatment. Paramount for all medical nutrition therapy is the attainment of optimal metabolic outcomes and the prevention and treatment of complications. For individuals with type 1 DM, the focus is on regulating insulin administration with a balanced diet to achieve and maintain a healthy body weight. A meal plan that is moderate in carbohydrates and low in saturated fat (<7% of total calories), with a focus on balanced meals is recommended. The amount (grams) and type (via the glycemic index, though controversial) of carbohydrates, whether accounted for by exchanges or carbohydrate counting, should be considered. It is imperative that patients understand the connection between carbohydrate intake and glucose control. In addition, patients with type 2 DM often require caloric restriction to promote weight loss, and portion size and frequency are often issues. Rather than a set diabetic diet, advocate a diet using foods that are within the financial reach and cultural milieu of the patient. As most patients with type 2 DM are overweight or obese, bedtime and between-meal snacks are not needed if pharmacologic management is appropriate.

#### Activity

In general, most patients with DM can benefit from increased activity. Aerobic exercise improves insulin sensitivity and glycemic control in the majority of individuals, and reduces cardiovascular risk factors, contributes to weight loss or maintenance, and improves well-being. The patient should choose an activity that she or he is likely to continue. Start exercise slowly in previously sedentary patients. It remains unclear which asymptomatic patients should be screened for CVD prior to the beginning of an exercise regimen. It may be reasonable in patients with long-standing disease (age >35 years, or >25 years old with DM ≥10 years), patients with multiple cardiovascular risk factors, presence of microvascular disease (especially renal disease), and patients with previous evidence of atherosclerotic disease should have a cardiovascular evaluation, probably including an

*Assay should be National Glycohemoglobin Standardization Program (NGSP) certified measurement and DCCT standardized. More stringent glycemic control may be appropriate if accomplished without significant hypoglycemia or adverse effects. Less stringent HbA1c goals may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovacular complications or comorbidities, at-risk elderly, dementia, or in younger children.

Postprandial glucose measurements should be made 1–2 hours after the beginning of the meal, generally the time of peak levels in patients with diabetes.

Vulnerability to hypoglycemia and relatively low risk of complication prior to puberty considered. Adolescents and young adults may have adult goals if without developmental and psychological issues, and if without excessive hypoglycemia.
electrocardiogram, with further workup related to CVD risk. In addition, several complications (uncontrolled hypertension, autonomic neuropathy, insulin resistance, and retinopathy) may require restrictions on the activities recommended. Physical activity goals include at least 150 minutes/week of moderate (50%–70% maximal heart rate) intensity exercise. In addition, resistance training, in patients without retinal contraindications, is recommended for 30 minutes 3 times/week.

**PHARMACOLOGIC THERAPY**

Until 1995, only two options for pharmacologic treatment were available for patients with diabetes: sulfonylureas (for type 2 DM only) and insulin (for type 1 or 2). Since 1995, a number of new oral agents, injectables, and insulins have been introduced in the United States.

Currently, eight classes of oral agents are approved for the treatment of type 2 diabetes: α-glucosidase inhibitors, biguanides, meglitinides, peroxisome proliferator activated receptor γ agonists (which are also commonly identified as thiazolidinediones or glitazones), dipeptidyl peptidase 4 (DPP-4) inhibitors, dopamine agonists, bile acid sequestrants, and sulfonylureas. Oral antidiabetic agents are often grouped according to their glucose-lowering mechanism of action. Biguanides and thiazolidinediones are often categorized as insulin sensitizers due to their ability to reduce insulin resistance. Sulfonylureas and meglitinides are often categorized as insulin secretagogues because they enhance endogenous insulin release.

Diabetes treatment options continue to evolve, with newer oral agents and non-insulin injectables potentially altering future algorithms for the treatment of diabetes. The subsequent sections describe the current antidiabetic medications that are available to treat type 1 and type 2 diabetes mellitus.

**Drug Class Information**

**Insulin Pharmacology.** Insulin is an anabolic and anticatabolic hormone. It plays major roles in protein, carbohydrate, and fat metabolism. For a complete review of insulin action, the reader is referred to a diabetes physiology text. Endogenously produced insulin is cleaved from the larger proinsulin peptide in the β cell to the active peptide of insulin and C-peptide, which can be used as a marker for endogenous insulin production. All commercially available insulin preparations contain only the active insulin peptide.

**Characteristics.** Characteristics that are commonly used to categorize insulins include source, strength, onset, and duration of action. Additionally, insulins may be characterized as analogs, defined as insulins that have had amino acids within the insulin molecule modified and/or “modifiers” added to impart particular physiochemical and pharmacokinetic advantages. Table 83–8 summarizes available insulin preparations.

- U-100 and U-500, 100 units/mL and 500 units/mL, respectively, are the strengths of injectable insulin currently available in the United States. U-500 regular insulin is available for individuals that may require large doses of insulin to control their diabetes. In the United States, all other insulins are available only in U-100 strength. For some type 1 diabetes patients who require extremely low doses of insulin, dilution of U-100 insulin to obtain accurate insulin doses may be necessary. Diluents and empty bottles can be obtained from the manufacturers for dilution.

Historically, insulin came from either beef or pork sources. Beef insulin differs by three amino acids and pork by one amino acid when compared to human insulin. Manufacturers in the United States have discontinued production of beef and pork source insulins as of December 2003, and now exclusively use recombinant DNA technology to manufacture insulin. Eli Lilly and Sanofi-Aventis currently use a non–disease-producing strain of *Escherichia coli* for synthesis of insulin; whereas Novo Nordisk uses *Saccharomyces cerevisiae*, or bakers’ yeast, for synthesis.

Purity of insulin refers to the amount of proinsulin and other impurities present in a given insulin product. Prior to 1980, most insulin contained enough impurities (300–10,000 ppm) to cause local reactions upon injection, as well as systemic adverse effects from antibody production. Modern technology has provided less expensive techniques to purify insulin. As a result, all insulin products contain ≤10 ppm of proinsulin, with purified preparations (all recombinant DNA human insulin and insulin analogs) containing <1 ppm of proinsulin.

Regular crystalline insulin naturally self-associates into a hexameric (six insulin molecules) structure when injected subcutaneously. Before absorption through a blood capillary can occur, the hexamer must dissociate first to dimers, and then to monomers. This principle is the premise for additives such as protamine and zinc described below, and modification of amino acids for insulin analogs. Lispro, aspart, and glulisine insulins dissociate rapidly to monomers, thus absorption is rapid. Lispro (B-28 lysine and B-29 proline human insulin; monomeric) insulin with two amino acids transposed, aspart (B-28 aspartic acid human insulin; mono- and dimeric) insulin with replacement of one amino acid, and glulisine (B-3 lysine and B-29 glutamic acid) are rapidly absorbed, peak faster, and have shorter durations of action when compared to regular insulin. Proteins tend to be insoluble near their isoelectric point, and glargine insulin uses this to prolong absorption. In comparison to human insulin, with an isoelectric point of 5.4, the analog glargine insulin (A-21 glycine, B-30a-arginine, B-30a L-arginine, and B-30b L-arginine human insulin) has an isoelectric point of 6.8. In the bottle, glargine is buffered to a pH of 4, a level at which it is completely soluble, resulting in a clear colorless solution. When injected into the neutral pH of the body, it rapidly forms microprecipitates that slowly dissolve into monomers and dimers which are then subsequently absorbed. The result is a long-acting, 24-hour duration insulin analog. Detemir, in contrast, attaches a C14 fatty acid (a 14 carbon fatty acid) at the B-29 position and removes the B-30 amino acid. This allows the fatty acid side chain to bind to interstitial albumin at the SQ injection site. Also, the formulation allows stronger hexamer (six molecules of insulin associated together) self associations, which prolong absorption. Once detemir dissociates from the interstitial albumin, it is free to enter a capillary, where it is again bound to albumin, which can further prolong action. It then travels to a site of action and interacts, after dissociation from albumin, with insulin receptors.

Insulin analogs are modified human insulin molecules, and safety is paramount for FDA approval. Key factors that should be considered in the approval process include local injection reactions, antigenicity, efficacy compared to human insulin, insulin receptor binding affinity, and insulin-like growth factor 1–receptor affinity (which is compared to that of human insulin to determine mitogenic potential).

**Pharmacokinetics.** Subcutaneous injection kinetics are dependent on onset, peak, and duration of action, and are summarized in Table 83–9. Absorption of insulin from a subcutaneous depot is dependent on several factors, including source of insulin, concentration of insulin, additives to the insulin preparations (e.g., zinc, protamine, etc.), blood flow to the area (rubbing of injection area, increased skin temperature, and exercise in muscles near the injection site may enhance absorption), and injection site. Regular or NPH insulin is commonly injected in (from most

rapid to slowest absorption): abdominal fat, posterior upper arms, lateral thigh area, and superior buttocks area. Insulin analogs, unlike regular or NPH insulin, appear to retain their kinetic profile at all sites of injection. U-500 regular insulin has a delayed onset, peak, and a longer duration of action when compared to U-100 insulin. Addition of protamine (NPH, NPL, and aspart protamine suspension) or excess zinc (historically lente or ultralente insulin) will delay onset, peak, and duration of the insulin’s effect. Variability in absorption, inconsistent suspension of the insulin by the patient or healthcare provider when drawing up a

*aLente and Ultralente insulin has been discontinued. 
*bDetemir is considered “flat” pharmacokinetically, and detemir has a slight peak, but both have exhibited peak effects during comparative testing, and these peak effects may necessitate changing therapy in a minority of type 1 DM patients.
*cSee text for further discussion.
dose, and inherent insulin action based on the pharmacokinetics of the products may all contribute to a labile glucose response. NPH and all suspension based insulins should be inverted or rolled gently at least 10 times to fully resuspend the insulin prior to each use.

As detemir insulin has a unique mechanism to prolong absorption, it should not be surprising that the pharmacokinetics are unique. Detemir insulin reported less intrapatient variability between injections (less “wobble” in insulin levels between injections) when compared with NPH or glargine insulin. This may be advantageous when variability in the insulin level may make a large difference in glycemic excursions, as in type 1 DM. It should be noted, at low dose (0.2 units/kg) the duration of action is approximately 14 to 16 hours, while at doses above 0.3 units/kg, it is close to 24 hours. In type 1 DM, 30%–50% of patients may require twice daily use of detemir insulin to cover 24 hour basal insulin needs, but this is unlikely to be an issue in type 2 DM patients, as they tend to use more units per day to attain glycemic goals. Direct comparative data between glargine insulin and detemir insulin is difficult to interpret, as detemir insulin was allowed to be dosed twice daily. Equivalent glycemic control was attained with either insulin. It is possible that glargine insulin in a minority of type 1 DM patients may pharmacokinetically require twice daily dosing, but this is poorly documented in the literature.

The half-life of an intravenous (IV) injection of regular insulin is about 9 minutes. Thus the effective duration of action of a single IV injection is short, and changes in IV insulin rates will reach steady state in approximately 45 minutes. Intravenous pharmacokinetics of other soluble insulins (lispro, aspart, glulisine, and even glargine) are similar to IV regular insulin, but they have no advantages over IV regular insulin and are more expensive. For completeness, aspart and glulisine are both FDA approved for intravenous use.

Insulin is degraded in the liver, muscle, and kidney. Liver deactivation is 20% to 50% in a single passage. Approximately 15% to 20% of insulin metabolism occurs in the kidney. This may partially explain the lower insulin dosage requirements in patients with endstage renal disease.

Currently, insulin must be injected to retain its glycemic lowering properties. Alternative absorption pathways, including pulmonary, topical, gastrointestinal, an even nasal are being explored. The first inhalation insulin was discontinued due to poor sales and subsequent reports of lung cancer, but Technosphere inhaled insulin (Afrezza) has been submitted to the FDA for review. The onset of action is similar to IV insulin, which is unique.

An educated patient in conjunction with a skilled practitioner can usually achieve excellent glycemic control with insulin therapy. Efficacy with insulin therapy is related to achieving glycemic control while minimizing the risk of potential side effects, specifically hypoglycemia and weight gain. Insulin is recommended in patients with extremely high fasting plasma glucose levels (>280–300 mg/dL) or HbA1c, patients with ketonuria or ketonemia, symptomatic patients with extremely high fasting plasma glucose levels (>280–300 mg/dL) or HbA1c, patients with ketonuria or ketonemia, symptomatic patients (weight loss with polyuria, polydipsia, and/or nocturia), gestational diabetes mellitus, pregnancy with diabetes, and if deemed appropriate by the clinician and patient.39–42

**Microvascular Complications.** Insulin has been shown to be as efficacious as any oral agent for treating DM. The United Kingdom Prospective Diabetes Study, which used sulfonylureas or insulin, showed equal efficacy in lowering the risk of microvascular events in newly diagnosed type 2 DM.42 Similarly, in type 1 DM, the Diabetes Control and Complications Trial showed efficacy in reducing microvascular complications.41

**Macrovacular Complications.** The connection between high insulin levels (hyperinsulinemia), insulin resistance, and cardiovascular events incorrectly leads some clinicians to believe that insulin therapy may cause macrovascular complications. The UKPDS and DCCT found no differences in macrovascular outcomes with intensive insulin therapy. One study, the Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction study43 reported reductions in mortality with insulin therapy. This group assessed the effect of an insulin-glucose infusion in type 2 DM patients who had experienced an acute myocardial infarction. Those randomized to insulin infusion followed by intensive insulin therapy lowered their absolute mortality risk by 11% over a mean follow-up period of approximately 3 years. This was most evident in subjects who were insulin-naive or had a low cardiovascular risk prior to the acute myocardial infarction.44 The importance of glycemic control in hospitalized patients is covered later in the chapter.

**Adverse Effects.** The most common adverse effects reported with insulin are hypoglycemia and weight gain. Hypoglycemia is more common in patients on intensive insulin therapy regimens versus those on less-intensive regimens. Also, patients with type 1 DM tend to have more hypoglycemic events compared to type 2 DM patients. In the UKPDS study, performed over 10 years, the percentage of diabetic patients that needed assistance (thirdparty or hospitalization) due to hypoglycemia was three times higher for severe hypoglycemia compared to conventional therapy. Glycemic goals should incorporate hypoglycemic risk versus the benefit of lowering the glucose when HbA1c levels are near normal, especially in type 1 DM.

Minimization of risk for patients on insulin should include education about the signs and symptoms of hypoglycemia, proper treatment of hypoglycemia, and blood glucose monitoring. Blood glucose monitoring is essential for those on insulin, and is particularly of value in patients with hypoglycemia unawareness. Patients with hypoglycemia unawareness do not experience the normal sympathetic symptoms of hypoglycemia (tachycardia, tremulousness, and often, sweating). Initial hypoglycemia symptoms are neuroglycopenic in nature (confusion, agitation, loss of consciousness, and/or progression to coma). Patients with hypoglycemia unawareness should at least temporarily raise their glycemic goals (requiring a reduction in insulin dose) and check their blood glucose level prior to any activities that may be dangerous with a low blood sugar (e.g., driving and certain sports, among others). Proper treatment of hypoglycemia dictates ingestion of carbohydrates, with glucose being preferred. Unconsciousness is an indication for either IV glucose, or glucagon injection, which increases glycogenolysis in the liver. Glucagon use would be appropriate in any situation in which the patient does not have or cannot have ready IV access for glucose administration. Education for reconstitution and injection of glucagon is recommended for close friends and family of a patient who has recurrent neuroglycopenic events. The patient and close contacts should be informed that it can take 10 to 15 minutes for the injection to start raising glucose levels, and patients often vomit during this time. Proper positioning to avoid aspiration should be emphasized.

Weight gain is predominantly from increased truncal fat, and tends to be related to daily dose and plasma insulin levels present. Weight gain is undesirable in most type 2 DM patients, but may be seen as beneficial in underweight patients with type 1 DM. Weight gain appears to be related to intensive insulin therapy, and can be somewhat minimized by physiologic replacement of insulin.

Two forms of lipodystrophy, though much less common today in people with diabetes, still occur. Lipohypertrophy is caused by many injections into the same injection site. Due to insulin’s anabolic actions, a raised fat mass is present at the injection site with
resultant variable insulin absorption. Lipodystrophy, in contrast, is thought to be due to insulin antibodies or allergic type-reactions with destruction of fat at the site of injection. Injection away from the site with more purified insulin is recommended, though reports of lipodystrophy have been reported with most insulin preparations. Anecdotal evidence has shown that specially formulated cromolyn may help to stabilize the allergic type of reaction.

One large database associated glargine insulin with a higher risk of breast cancer, and possibly colon and pancreatic cancer, but other large database studies have shown no such association. Glargine in vitro has a higher affinity for IGF-1 than regular human insulin, which could theoretically explain the increased risk of cancer. However, in the observational, retrospective study, patients on glargine were older than patients on the comparator NPH insulin, which may explain the increased cancer rate observed. Supporting this premise, when glargine was used in intensive insulin therapy regimens in healthier populations, no such association was seen.

**Drug–Drug Interactions.** There are no significant drug–drug interactions with injected insulin, though other medications that may affect glucose control can be considered. Detemir does not have albumin binding interactions, as it occupies only a small percent of albumin binding sites. Table 83–10 lists common medications known to affect blood glucose levels.

**Dosing and Administration.** The dose of insulin for any person with altered glucose metabolism must be individualized. In type 1 DM, the average daily requirement for insulin is 0.5 to 0.6 units/kg, with approximately 50% being delivered as basal insulin, and the remaining 50% dedicated to meal coverage. During the honey-moon phase it may fall to 0.1 to 0.4 units/kg. During acute illness the remaining 50% dedicated to meal coverage. During the honey-moon phase it may fall to 0.1 to 0.4 units/kg. During acute illness 50% of albumin binding sites.

There are no significant drug–drug interactions with injected insulin, though other medications that may affect glucose control can be considered. Detemir does not have albumin binding interactions, as it occupies only a small percent of albumin binding sites. Table 83–10 lists common medications known to affect blood glucose levels.

*This list is not inclusive of all medications reported to cause glucose changes.

**Storage.** It is recommended that unopened injectable insulin be refrigerated (36°–46°F) prior to use. The manufacturer’s expiration date printed on the insulin is used for unopened, refrigerated insulin. Once the insulin is in use, the manufacturer-recommended expiration dates will vary based on the insulin and delivery device. Table 83–8 outlines manufacturer-recommended expiration dates for room temperature (59°–86°F) insulin. For financial reasons, patients may attempt to use insulins longer than their expiration dates, but careful attention must be paid to monitoring for glycemic control deterioration and signs of insulin decay (clumping, precipitates, discoloration, etc.) if this is attempted.

**Glucagon-Like Peptide 1 Agonists**

**Exenatide Pharmacology.** Exendin 4 is a 39-amino acid peptide isolated from the saliva of the Gila monster (Heloderma suspectum) and shares approximately 50% amino acid sequence with human glucagon-like peptide 1 (GLP-1). Exenatide is the synthetic version of naturally occurring exendin 4. Exenatide (Byetta) has been shown to bind to GLP-1 receptors in many parts of the body including the brain and pancreas. Exenatide and GLP-1 have common glucoregulatory actions. Exenatide enhances glucose-dependent insulin secretion while suppressing inappropriately high postprandial glucagon secretion in the presence of elevated glucose concentrations, resulting in a reduction in hepatic glucose production. Exenatide increases satiety, which may result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition. The GLP-1 receptor activity is pharmacologic, and is approximately 3 to 4 times the normal peak physiologic GLP-1 activity. This is necessary to obtain gastric emptying and satiety effects, which are not seen at physiologic GLP-1 levels.

**Pharmacokinetics.** Exenatide concentrations are detectable in plasma within 10 to 15 minutes after subcutaneous injection, and the drug has a t½ of ~2 hours and a plasma half life of ~3.3 to 4.0 hours. Exenatide plasma concentrations increase in a dose-dependent manner and plasma exenatide concentrations are detectable for up to 10 hours postinjection, though pharmacodynamically, effects last for approximately 6 hours. Bioavailability of exenatide after injection in the abdomen, upper arm, or the thigh is similar. Elimination of exenatide is primarily by glomerular filtration with subsequent proteolytic degradation. When exenatide is administered to subjects with worsening degrees of renal insufficiency, there is a progressive prolongation of the half-life, and in dialysis patients, plasma clearance of exenatide is markedly reduced. The incidence of gastrointestinal side effects appears to be increased in individuals with impaired renal function, possibly due to higher plasma levels, thus caution is advised.

No significant differences in exenatide pharmacokinetics have been observed with obesity, race, gender, or advancing age (up to 73 years old).

**Efficacy.** The average HbA1c reduction is approximately 0.9% with exenatide, though, similar to oral agents, it is dependent upon the baseline HbA1c values. Three phase III trials reported similar HbA1c reduction in patients on metformin, sulfonylureas, or both. It is recommended to lower the sulfonylurea dose only if GLP-1 agonists are started with near normal glucose levels. Sulfonylureas release insulin in a non-glucose dependent fashion and can cause occasional severe hypoglycemia. Exenatide significantly decreases postprandial glucose excursions, but has only a modest effect on
failing plasma glucose values. If a patient has significant elevations in fasting plasma glucose levels, these should be corrected with other agents, and the exenatide added on. Exenatide may aid some patients’ efforts to lose weight. The average weight loss in controlled trials was 1 to 2 kg over 30 weeks, without dietary advice being given to the patients, though long-term, open-label follow-up on 10 mcg BID shows continued and sustained weight loss for at least 3 years. Approximately 84% of patients on exenatide lost some weight. Exenatide, through decreasing appetite and slowing gastric emptying, may reduce the number of calories a patient eats at a meal. If a patient does not decrease calorie intake, as exenatide does not increase caloric expenditure, no weight loss is likely to occur.

**Microvascular Complications.** Exenatide reduces the HbA1c level, which has been shown to be related to the risk of microvascular complications.

**Macrovascular Complications.** No randomized clinical trials have examined the effect of exenatide on cardiovascular outcomes. Meta-analysis data reported a 30% (P = NS) reduction in the risk of cardiovascular events. Improvements in several cardiovascular risk factors have been reported. Plasma triglycerides (–37 ± 10 mg/dL) decreased, and plasma HDL cholesterol (+4.5 ± 0.4 mg/dL) increased on open-label exenatide 10 mcg BID. Nonsignificant reductions in systolic and diastolic blood pressure were observed in the whole population, though a significant reduction was seen in subjects with above normal systolic blood pressure. The greatest improvement in cardiovascular risk factors was, in general, seen in subjects who had the greatest weight loss.46

**Adverse Effects.** The most common adverse effects associated with exenatide are gastrointestinal in nature. Nausea occurs in ~40% of subjects on 5 mcg, and ~45% to 50% of subjects on 10 mcg BID. Vomiting or diarrhea occurs in approximately 10% of patients placed on exenatide. Gastrointestinal adverse effects appear to decrease over time, but approximately 1 in 20 patients may have prolonged problems with one of the above side effects, possibly requiring discontinuation. As these adverse effects appear to be dose related, the patient should be started on a 5 mcg BID and titrated to 10 mcg BID only if the adverse effects are mostly gone. Also, when the patient is increased to the 10 mcg BID dose, these adverse effects may recur for a short period of time. Many episodes of nausea would be better characterized as stomach fullness, and patients should be instructed to eat slowly and stop eating when full, or risk nausea/vomiting. Also, weight loss appears not to be related to adverse effects, but rather to a reduction in calories consumed. Exenatide provides glucose-dependent insulin secretion, thus hypoglycemic rates when combined with metformin or a thiazolidinedione are not substantially increased, but when combined with a sulfonylurea or insulin, significant hypoglycemia may occur. Though exenatide reduces glucagon when the glucose is high, no suppression of counter-regulatory hormones has been noted during hypoglycemia. Exenatide antibodies can occur, but generally decrease over time and do not affect glycemic control. In approximately 5% of patients, titters may increase over time, resulting in a blunting of glycemic control in about half of these patients. Exenatide has been associated with the serious adverse effect of acute pancreatitis, but this has not been shown to be causal. Further study is needed, but several important points should be noted: (1) type 2 DM patients have many risk factors for pancreatitis such as gallstones, hypertriglyceridemia, obesity, and concommitant medication use; (2) GLP-1 agonists can mask initial signs of pancreatitis, as nausea, vomiting, and abdominal pain are common signs of pancreatitis; and (3) large database studies have not linked exenatide to a higher rate of acute pancreatitis. Clinically, do not use exenatide in a patient with a history of pancreatitis, and if a patient with abdominal pain, nausea, and/or vomiting presents it is best to discontinue exenatide temporarily and clinically confirm that it is not a sign of a more serious underlying problem. Exenatide given twice daily does not change the risk of thyroid C-cell tumors in rats, and no signal for C-cell tumors has been reported in humans.

**Drug Interactions.** Exenatide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that may be affected include oral pain medications and antibiotics dependent on concentration dependent killing. If rapid absorption of the medication is necessary, it is best to take the medication one hour before, or at least 3 hours after the injection of exenatide. In addition, if the patient has gastroparesis, exenatide is not recommended.

**Dosing and Administration.** Exenatide dosing should be started with 5 mcg BID, and titrated to 10 mcg BID in 1 month or when tolerability allows and if warranted for glycemic control. Exenatide should be injected 0 to 60 minutes before the morning and evening meals. If the patient does not eat breakfast, they may take the first injection of the day at lunch. The peak effect of exenatide is at approximately 2 hours, so anecdotally the patient may get better appetite suppression if injected an hour prior to the meal. Storage and dosage availability information can be found in Table 83–8.

**Liraglutide Pharmacology.** Liraglutide (Victoza) is a GLP-1 receptor agonist. Liraglutide enhances glucose-dependent insulin secretion while suppressing inappropriately high glucagon secretion in the presence of elevated glucose concentrations, resulting in a reduction in hepatic glucose production. Liraglutide reduces food intake, which may result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition. During hypoglycemia, liraglutide does not stimulate insulin secretion and does not inhibit the release of the counterregulatory hormone glucagon. Liraglutide is produced through recombinant DNA technology, similar to the way insulin is made by the manufacturer, Novo Nordisk. Liraglutide has 97% amino acid sequence homology to endogenous GLP-1, with the only alteration being an arginine for lysine at position 34. A C-16 fatty acid (palmitic acid) is attached at position 26 (with a glutamic amino acid spacer to optimize GLP-1 receptor interaction) so that liraglutide can bind noncovalently to albumin, prolonging the half-life.

**Pharmacokinetics.** Self-association into a heptameric structure, and binding to albumin first in the interstitial space, then the blood, then the interstitial space around the GLP-1 receptor. Liraglutide enhances glucose-dependent insulin secretion and does not stimulate glucagon secretion, better matches the glucose disposition. During hypoglycemia, liraglutide does not stimulate insulin secretion and does not inhibit the release of the counterregulatory hormone glucagon. Liraglutide is produced through recombinant DNA technology, similar to the way insulin is made by the manufacturer, Novo Nordisk. Liraglutide has 97% amino acid sequence homology to endogenous GLP-1, with the only alteration being an arginine for lysine at position 34. A C-16 fatty acid (palmitic acid) is attached at position 26 (with a glutamic amino acid spacer to optimize GLP-1 receptor interaction) so that liraglutide can bind noncovalently to albumin, prolonging the half-life.

rosiglitazone. HbA\textsubscript{lc} reduction with monotherapy 1.2 mg or 1.8 mg daily dose was significantly better than glimepiride 8 mg daily over 52 weeks. Liraglutide 1.2 mg (−0.9%) and 1.8 mg (−1.1%) daily sustained HbA\textsubscript{lc} reductions over 2 years, but glimepiride 8 mg daily (−0.6%) did not sustain the HbA\textsubscript{lc} reduction. Liraglutide consistently lowered the fasting plasma glucose level by approximately 25 to 40 mg/dL, and postprandial plasma glucose levels are reduced similarly. Due to the longer half-life, liraglutide can suppress glucagon overnight, which improves the fasting plasma glucose. Similar to exenatide, liraglutide treated patients may lose weight. The average weight loss in controlled trials was 1 to 3 kg over 26 weeks, and weight loss achieved appeared to be sustained through 2 years. Liraglutide, through decreasing appetite and slowing gastric emptying, may reduce the number of calories a patient eats at a meal.

**Microvascular Complications.** Liraglutide reduces the HbA\textsubscript{lc} level, which has been shown to be related to the risk of microvascular complications.

**Macrovascular Complications.** No published clinical trials have examined the effect of liraglutide on cardiovascular outcomes, though no signal of cardiovascular harm was noted upon FDA approval.

**Adverse Effects.** The most common adverse effects associated with liraglutide are gastrointestinal in nature. Nausea occurs in ~11% to 29% of subjects on 1.2 mg, and 14% to 40% of subjects on 1.8 mg daily. Vomiting may occur in approximately 5% of subjects, and diarrhea occurs in approximately 8% to 15% of patients placed on liraglutide. Gastrointestinal adverse effects appear to decrease over time, but approximately 5% to 10% of subjects withdrew due to gastrointestinal side effects. As these adverse effects appear to be dose related, the patient should be titrated from 0.6 mg, to 1.2 mg, and to 1.8 mg as tolerated. Randomized trials did not allow for individualized titration, and likely had worse tolerability that can be obtained clinically by individualization of titration. Many episodes of nausea would be better characterized as stomach fullness, and patients should be instructed to eat slowly and stop eating when full, or risk nausea/vomiting. Liraglutide provides glucose-dependent insulin secretion, and hypoglycemic rates when combined with metformin ± a thiazolidinedione are not substantially increased, but when combined with a sulfonylurea or insulin, significant hypoglycemia may occur. When combined with a sulfonylurea, the rates of hypoglycemia were similar between addition of liraglutide or glargine insulin. Liraglutide antibodies can occur (4%–13%), but the rates are generally low and do not affect glycemic control or risk of side effects.

Liraglutide has been associated with the serious adverse event of acute pancreatitis, but this risk has not been shown to be causal. Further study is needed, but type 2 DM patients have many risk factors for pancreatitis such as gallstones, hypertriglyceridemia, obesity, and concomitant medication use. GLP-1 agonists can mask initial signs of pancreatitis, as nausea, vomiting, and abdominal pain are common signs of pancreatitis. Clinically, do not use liraglutide in a patient with a history of pancreatitis. If a patient with abdominal pain, nausea, and/or vomiting presents, it is best to discontinue liraglutide temporarily and proceed with an initial workup for pancreatitis.

A black box warning about thyroid C-cell tumors is listed on the package insert of liraglutide. Rodent models reported a higher risk of C-cell tumors of the thyroid, including medullary thyroid carcinoma. Medullary thyroid carcinoma, if not caught early, has high mortality rates, but rodents may simply be a poor model to study this effect as they express many more GLP-1 receptors on their thyroid than human beings. In addition, calcitonin, a marker used to screen for C-cell tumors, may increase by a non-clinically significant amount in select patients. No signal for C-cell tumors in humans or non-human primates has been noted, and as clinical use increases, this will be reexamined. No monitoring is currently recommended, but liraglutide is contraindicated in patients with a personal or family history of medullary thyroid cancer, or if they have a history of multiple endocrine tumors.

**Drug Interactions.** Liraglutide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that may be affected include oral pain medications and antibiotics dependent on threshold levels for efficacy. If rapid absorption of the medication is necessary, it is best to take the medication 1 hour before, or at least 3 hours after the injection. Liraglutide may worsen gastroparesis and clinically it may not be prudent to use in this patient population.

**Dosing and Administration.** Dosing of liraglutide should be at 0.6 mg daily for ≥1 week, and then increased to 1.2 mg daily for ≥1 week. Patients may be maintained on the 1.2-mg dose, or increased to the maximum dose of 1.8 mg daily after ≥1 week. The 0.6-mg dose is considered a titration dose, and does not reduce the HbA\textsubscript{lc} substantially in the majority of patients. This titration is recommended to improve gastrointestinal tolerability, and titration should be individualized based on side effects and clinical response. Dosing is daily, and can be given independent of meals. As with exenatide, the reduction in insulin secretagogues may be necessary if the patient is near glycemic goal. Storage and dosage availability information can be found in Table 83–8.

**Exenatide versus Liraglutide.** In a head-to-head trial in type 2 DM subjects given metformin, sulfonylurea, or both over 26 weeks, liraglutide 1.8 mg daily lowered HbA\textsubscript{lc} (−1.1%) significantly more than exenatide 10 mcg BID (−0.8%). Liraglutide was better at reduction of fasting plasma glucose, but exenatide was slightly better at reduction of postprandial glucose. Both resulted in approximately 3-kg weight loss, and minor hypoglycemic events were slightly less frequent with liraglutide (26%) than with exenatide BID (34%). Nausea rates were similar for liraglutide (26%) and exenatide (28%), but the rate of persistence was lower with liraglutide, being below 10% by week 6, whereas exenatide did not reach this level until after week 22. No significant changes in calcitonin were noted and there were no reports of pancreatitis, but a small, significant increase in heart rate was noted with liraglutide (+3.3 beats per minute) versus exenatide (+0.7 beats per minute).

**Amylinomimetic**

**Pramlintide Pharmacology.** Pramlintide (Symlin) is an antihyperglycemic agent used in patients currently treated with insulin. Pramlintide is a synthetic analog of amylin (amylinomimetic), a neurohormone co-secreted from the β cells with insulin. Amylin is very low or absent in type 1 DM, and lower than normal in type 2 DM patients requiring insulin therapy. Pramlintide is provided as a 37-amino acid polypeptide, which differs in amino acid sequence from human amylin by replacement positions 25 (alanine), 28 (serine), and 29 (serine) with proline. Pramlintide suppresses inappropriately high postprandial glucagon secretion, increases satiety, which may result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition.

**Pharmacokinetics.** The absolute bioavailability of pramlintide after subcutaneous injection is 30% to 40%. The \( t_{1/2} \) is approximately 20 minutes, but the \( C_{max} \) is dose dependent and appears to be linear. The \( t_{max} \) is approximately 45 minutes, thus the pharmacodynamic duration of action is about 3 to 4 hours. Pramlintide does not extensively bind to albumin, and should not have significant binding interactions. Metabolism is primarily by the kidneys, and one active metabolite (2-37 pramlintide) has a similar half-life as
the parent compound. No accumulation has been seen in renal insufficiency, but caution is advised. Injection into the arm may increase exposure and variability of absorption, so injection into the abdomen or thigh is recommended. Moderate to severe renal insufficiency does not affect exposure.

**Efficacy.** The average HbA₁c reduction is approximately 0.6% with pramlintide, though optimization of the insulin and pramlintide doses may result in further drops in HbA₁c. If the 120-mcg dose is used in type 2 DM patients on insulin, it may also result in 1.5-kg weight loss. In type 1 DM patients, the average reduction in HbA₁c was 0.4% to 0.5%. Prandial pramlintide added versus rapid-acting insulin in type 2 DM subjects uncontrolled on basal insulin reported similar efficacy, but with no weight gain, compared with ~5-kg weight gain with rapid-acting insulin. Pramlintide decreases prandial glucose excursions, but has little effect on the fasting plasma glucose concentration. When pramlintide is injected before the meal, gastric emptying may delay absorption of mealtime nutrients, necessitating delay of rapid-acting insulin. This may be overcome by injecting the meal-time insulin at the conclusion of the meal, or whenever the blood glucose starts to rise. The average weight loss in controlled trials was 1 to 2 kg, without dietary advice being given to the patients. Pramlintide, through decreasing appetite and slowing gastric emptying, may reduce the number of calories a patient eats at a meal.

**Microvascular Complications.** Pramlintide reduces the HbA₁c level, which has been shown to be related to the risk of microvascular complications.

**Macrovascular Complications.** No published clinical trials have examined the effect of pramlintide on cardiovascular outcomes.

**Adverse Effects.** The most common adverse effects associated with pramlintide are gastrointestinal in nature. Nausea occurs in ~20% of type 2 DM patients, and vomiting or anorexia occurs in approximately 10% of type 1 or type 2 DM patients. Nausea is more common in type 1 DM, occurring in ~40% to 50% of patients. The higher rate in type 1 DM related to gastrointestinal adverse effects appear to decrease over time and are dose related, thus starting at a low dose and slowly titrating as tolerated is recommended. Pramlintide alone does not cause hypoglycemia, but it is indicated for use in patients on insulin, thus hypoglycemia can occur. The risk of severe hypoglycemia early in therapy is higher in type 1 DM than in type 2 DM patients. A 2-fold increase in severe hypoglycemic reactions in type 1 DM patients has been reported.

**Drug Interactions.** Pramlintide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that may be affected include oral pain medications and antibiotics dependent on threshold levels for efficacy. If rapid absorption of the medication is necessary, it is best to take the medication 1 hour before, or at least 3 hours after the injection of pramlintide.

**Dosing and Administration.** Pramlintide dosing varies in type 1 and type 2 DM. It is imperative that the prandial insulin dose, if used, be reduced 30% to 50% when pramlintide is started to minimize severe hypoglycemic reactions. Basal insulin may need to be adjusted only if the fasting plasma glucose is close to normal. In type 2 DM, the starting dose is 60 mcg prior to meals, and may be titrated to the maximally recommended 120-mcg dose as tolerated and warranted based on postprandial plasma glucose concentrations. In type 1 DM dosing starts at 15 mcg prior to meals, and can be titrated up in 15-mcg increments to a maximum of 60 mcg prior to each meal if tolerated and warranted. Snacks may or may not need to be covered with pramlintide (recommended if ≥2250 kcal or ≥30 g of carbohydrate is eaten). Pramlintide in a vial allows individualization of titration at even smaller increments (by units) than the package insert recommends, which may be useful in some type 1 DM patients. Each 2.5 units on a U-100 insulin syringe = 15 mcg of pramlintide. In addition, pramlintide has a pH of 4, and it is not recommended that pramlintide be mixed with any other insulin, thus this potentially adds additional injections a day. The addition of a pen device does help with the extra injections, but does not allow for smaller than recommended titrations. Storage information can be found in Table 83–8.

**Sulfonylureas Pharmacology.** The primary mechanism of action of sulfonylureas is enhancement of insulin secretion. Sulfonylureas bind to a specific sulfonylurea receptor (SUR) on pancreatic β cells. Binding closes an adenosine triphosphate-dependent K⁺ channel, leading to decreased potassium efflux and subsequent depolarization of the membrane. Voltage-dependent Ca²⁺ channels open and allow an inward flux of Ca²⁺. Increases in intracellular Ca²⁺ bind to calmodulin on insulin secretory granules, causing translocation of secretory granules of insulin to the cell surface and resultant exocytosis of the granule of insulin. Elevated secretion of insulin from the pancreas travels via the portal vein and subsequently suppresses hepatic glucose production.

**Classification.** Sulfonylureas are classified as first-generation and second-generation agents. The classification scheme is largely derived from differences in relative potency, relative potential for selective side effects, and differences in binding to serum proteins (i.e., risk for protein-binding displacement drug interactions). First-generation agents consist of acetohexamide, chlorpropamide, tolazamide, and tolbutamide. Each of these agents is lower in potency relative to the second-generation drugs: glibenclamide, glipizide, and glyburide (Table 83–11). It is important to recognize that all sulfonylureas are equally effective at lowering blood glucose when administered in equipotent doses.

**Pharmacokinetics.** All sulfonylureas are metabolized in the liver; some to active, others to inactive metabolites (see Table 83–11). Cytochrome P450 (CYP450) 2C9 is involved with the hepatic metabolism of the majority of sulfonylureas. Agents with active metabolites or parent drug that are renally excreted require dosage adjustment or use with caution in patients with compromised renal function. The half-life of the sulfonylurea also relates directly to the risk for hypoglycemia. The hypoglycemic potential is therefore higher with chlorpropamide and glyburide. The long duration of effect of chlorpropamide may be particularly problematic in elderly individuals, whose renal function declines with age, and therefore it has great potential for accumulation, resulting in severe and protracted hypoglycemia. Individuals at high risk for hypoglycemia (e.g., elderly individuals and those with renal insufficiency or advanced liver disease) should be started at a very low dose of a sulfonylurea with a short half-life. Hypoglycemia on low-dose sulfonylureas may dictate a therapy without the risk of hypoglycemia, or a short-acting insulin secretagogue (nateglinide or repaglinide).

**Efficacy.** As mentioned earlier, when given in equipotent doses, all sulfonylureas are equally effective at lowering blood glucose. On average, HbA₁c will fall 1.5% to 2%, with fasting plasma glucose reductions of 60 to 70 mg/dL, but is dependent on baseline values. A majority of patients will not reach glycemic goals with sulfonylurea monotherapy. Patients who fail sulfonylurea usually fall into two groups: Those with low C-peptide levels and high (>250 mg/dL) fasting plasma glucose (FPG) levels. These patients are often primary failures on sulfonylureas (<30 mg/dL drop of FPG) and have significant glucose toxicity or slow-developing type 1 DM. The other group is those with a good initial response (>30 mg/dL drop of FPG), but which is insufficient to reach their glycemic goals. Over 75% of patients fall into the second group. Factors that portend a positive response include newly diagnosed patients with no indicators of type

**Drug Interactions with Sulfonylureas**

SUMMARIZES THEM BY PROPOSED HYPOGLYCENIA. SUBSTANTIAL AMOUNTS OF WEIGHT ARE ALSO MORE LIKELY TO EXPERIENCE NETICS SECTION, THOSE WHO SKIP MEALS, EXERCISE VIGOROUSLY, OR LOSE ADDITION TO THE HIGH-RISK INDIVIDUALS OUTLINED IN THE PHARMACOKINETICS SECTION, THOSE WHO SKIP MEALS, EXERCISE VIGOROUSLY, OR LOSE

**Adverse Effects.** The most common side effect of sulfonylureas is hypoglycemia. The pretreatment fasting plasma glucose is a strong predictor of hypoglycemic potential. The lower the FPG is upon initiation, the higher the potential for hypoglycemia. Also, in addition to the high-risk individuals outlined in the pharmacokinetics section, those who skip meals, exercise vigorously, or lose substantial amounts of weight are also more likely to experience hypoglycemia.

Hyponatremia (serum sodium <129 mEq/L) is reportedly associated with tolbutamide, but it is most common with chlorpropamide and occurs in as many as 3% of individuals treated. An increase in antidiuretic hormone secretion is the mechanism for hyponatremia. Risk factors include age >60 years, female gender, and concomitant use of thiazide diuretics.

Weight gain is common with sulfonylureas. In essence, patients who are no longer glycosuric and who do not reduce caloric intake with improvement of blood glucose will store excess calories. Other notable, although much less common, adverse effects of sulfonylureas are skin rash, hemolytic anemia, gastrointestinal upset, and cholestasis. Disulfiram-type reactions and flushing have been implicated in blocking ischemic preconditioning via K⁺ channel closure in the heart. Ischemic preconditioning is the premise that prior ischemia in cardiac tissue can provide greater tolerance of subsequent ischemia. Thus, patients with heart disease potentially have one compensatory mechanism to protect the heart from ischemia blocked. Conclusions are controversial and readers are referred to the pertinent articles for further discussion.

1 DM, high fasting C-peptide levels, and moderate fasting hyperglycemia (<250 mg/dL). If glycemic goals are met, a secondary failure rate of approximately 5% to 7% per year can be expected.

**Microvascular Complications.** Sulfonylureas showed a reduction of microvascular complications in type 2 DM patients in the UKPDS. A more in-depth discussion follows later in the chapter.

**Macrovascular Complications.** The UKPDS reported no significant benefit or harm in newly diagnosed type 2 DM patients given sulfonylureas over 10 years. The University Group Diabetes Program study documented higher rates of coronary artery disease in type 2 patients given tolbutamide, when compared with patients given insulin or placebo, though this study has been widely criticized. Some sulfonylureas bind to the SUR-2A receptor that is found in cardiac tissue. Binding to the SUR-2A receptor has been implicated in blocking ischemic preconditioning via K⁺ channel closure in the heart. Ischemic preconditioning is the premise that prior ischemia in cardiac tissue can provide greater tolerance of subsequent ischemia. Thus, patients with heart disease potentially have one compensatory mechanism to protect the heart from ischemia blocked. Conclusions are controversial and readers are referred to the pertinent articles for further discussion.

*Many of these drug interactions may be metabolism-based.

†Inducer.

Reproduced from Gerich. 1
changes should occur shortly after the interacting medication is given, as the concentration of free (thus active) sulfonylurea will acutely increase. First-generation sulfonylureas, which bind to proteins ionically, are more likely to cause drug–drug interactions than second-generation sulfonylureas, which bind nonionically.32 The clinical importance of protein-binding interactions has been questioned, as the majority of these drug interactions have been found to be truly due to hepatic metabolism. Drugs that are inducers or inhibitors of CYP450 2C9 should be monitored carefully when used with a sulfonylurea. Additionally, other drugs known to alter blood glucose should be considered (see Table 83–10).

**Dosing and Administration.** The usual starting dose and maximum dose of sulfonylureas are summarized in Table 83–11. Lower dosages are recommended for most agents in elderly patients and those with compromised renal or hepatic function. The dosage should be titrated every 1 to 2 weeks (use a longer interval with chlorpropamide) to achieve glycemic goals. This is possible due to the rapid increase of insulin secretion in response to the sulfonylurea. Of note, immediate-release glipizide’s maximal dose is 40 mg/day, but its maximal effective dose is about 10 to 15 mg/day. The maximal effective dose of sulfonylureas tends to be about 60% to 75% of their stated maximum dose.

**Short-Acting Insulin Secretagogues.** *Pharmacology.* Though the binding site is adjacent to the binding site of sulfonylureas, nateglinide and repaglinide stimulate insulin secretion from the β cells of the pancreas, similarly to sulfonylureas. Repaglinide, a benzoic acid derivative, and nateglinide, a phenylalanine amino acid derivative, both require the presence of glucose to stimulate insulin secretion. As glucose levels diminish to normal, stimulated insulin secretion diminishes.

**Pharmacokinetics.** Both nateglinide and repaglinide are rapid-acting insulin secretagogues that are rapidly absorbed (~0.5–1 hour) and have a short half-life (1–1.5 hours). Nateglinide is highly protein-bound, primarily to albumin, but also to α1-acid glycoprotein. Nateglinide is predominantly metabolized by CYP2C9 (70%) and CYP3A4 (30%) to less active metabolites. Glucuronide conjugation then allows rapid renal elimination. No dosage adjustment is needed in moderate to severe renal insufficiency. Repaglinide is highly protein bound, and is mainly metabolized by oxidative metabolism and glucuronidation. The CYP3A4 and 2C8 system have been shown to be involved with metabolism. Approximately 90% of repaglinide is eliminated in the feces, with only 10% found in the urine. Moderate to severe renal insufficiency does not appear to affect repaglinide, but moderate to severe hepatic impairment may prolong exposure.

**Efficacy.** In monotherapy, both significantly reduce postprandial glucose excursions and reduce HbA1c levels. Repaglinide, dosed 4 mg 3 times a day, when compared with glyburide in diet-treated, drug-naïve patients reduced HbA1c levels less (1% vs 2.4%, from baseline, respectively).33 Nateglinide, dosed 120 mg 3 times a day in a similar population reduced HbA1c values by 0.8%.34 The lower efficacy of these agents versus sulfonylureas should be considered when patients are >1% above their HbA1c goal. These agents can be used to provide increased insulin secretion during meals, when it is needed, in patients close to glycemic goals. Also, it should be noted that addition of either agent to a sulfonylurea will not result in any improvement in glycemic parameters.

**Adverse Effects.** Hypoglycemia is the main side effect noted with both agents. Hypoglycemic risk appears to be less versus sulfonylureas. In part, this is due to the glucose-sensitive release of insulin. If the glucose concentration is normal, less glucose-stimulated release of insulin will occur. In two separate studies, nateglinide rates of hypoglycemia were 3% and repaglinide 15% versus glyburide and glipizide rates of 15% and 19%, respectively. Weight gain of 2 to 3 kg has been noted with repaglinide, whereas weight gain with nateglinide appears to be <1 kg.

**Drug Interactions.** Glycemic control and hypoglycemia should be closely monitored when glucuronidation inhibitors are given with repaglinide. Gemfibrozil, a medication used to treat hypertriglyceridemia in DM, more than doubles the half-life of repaglinide and has resulted in prolonged hypoglycemic reactions. Gemfibrozil is a potent glucuronidation inhibitor and CYP2C8 inhibitor. Trimethoprim, a CYP2C8 inhibitor, increased repaglinide levels by 60%. Nateglinide appears to be a weak inhibitor of CYP2C9 based on tolbutamide metabolism. Though no significant drug–drug interactions have been reported, caution should be used with strong CYP2C9 and CYP3A4 inhibitors.

**Dosing and Administration.** Nateglinide and repaglinide should be dosed prior to each meal (up to 30 minutes prior). The recommended starting dose for repaglinide is 0.5 mg in subjects with HbA1c <8% or treatment-naïve patients, increased weekly to a total maximum daily dose of 16 mg (see Table 83–11). The maximal effective dose of repaglinide is likely 2 mg with each meal, as a dose of 1 mg prior to each meal provides approximately 90% of the maximal glucose-lowering effect. Nateglinide should be dosed at 120 mg prior to meals, and does not require titration. A 60-mg dose is available, but the HbA1c decrement is small (0.3%–0.5%). If a meal is skipped, the medication can be skipped, and meals extremely low in carbohydrate content may not need a dose. Both agents may be used in patients with renal insufficiency, and may fit into therapy in patients in need of an insulin secretagogue but have hypoglycemia to sulfonylureas, mode to severe renal insufficiency, well-controlled diabetes, but with erratic meal schedules.

**Biguanides.** *Pharmacology.* Metformin is the only biguanide available in the United States. Metformin has been used clinically for more than 50 years, and has been approved in the United States since 1995. Metformin enhances insulin sensitivity of both hepatic and peripheral (muscle) tissues. This allows for an increased uptake of glucose into these insulin-sensitive tissues. The exact mechanisms of how metformin accomplishes insulin sensitization are still being investigated, though adenosine 5′-monophosphate–activated protein kinase activity, tyrosine kinase activity enhancement, and glucose transporter 4 all play a part. Metformin has no direct effect on the β cells, though insulin levels are reduced, reflecting increases in insulin sensitivity.

**Pharmacokinetics.** Metformin has approximately 50% to 60% oral bioavailability, low lipid solubility, and a volume of distribution that approximates body water. Metformin is not metabolized and does not bind to plasma proteins. Metformin is eliminated by renal tubular secretion and glomerular filtration. The average half-life of metformin is 6 hours, though pharmacodynamically, metformin’s antihyperglycemic effects last more than 24 hours.

**Efficacy.** Metformin consistently reduces HbA1c levels by 1.5% to 2.0%, fasting plasma glucose levels by 60 to 80 mg/dL, and retains the ability to reduce FPG levels when they are extremely high (>300 mg/dL). The sulfonylureas’ ability to stimulate insulin release from β cells at extremely high glucose levels is often impaired, a concept commonly referred to as *glucose toxicity*. Metformin also has positive effects on several components of the insulin resistance syndrome. Metformin decreases plasma triglycerides and LDL-C by approximately 8% to 15%, as well increasing HDL-C very modestly (2%). Metformin reduces levels of PAI-1 and causes a modest reduction in weight (2–3 kg). In preliminary findings, metformin may also lower the risk of pancreatic, colon, and breast cancer in type 2 DM patients. Metformin, through adenosine 5′-monophosphate–activated protein kinase activity, may act as a growth inhibitor in some cancers and help to kill cancer “stem cells,” which are resistant to chemotherapy.
Microvascular Complications. Metformin (n = 342) was compared with intensive glucose control with insulin or sulfonylureas in the UKPDS. No significant differences were seen between therapies with regard to reducing microvascular complications, but the power of the study is questionable.

Macrovascular Complications. Metformin significantly reduced all-cause mortality and risk of stroke versus intensive treatment with sulfonylureas or insulin. Metformin also reduced diabetes-related death and myocardial infarctions versus the conventional treatment arm of the UKPDS. It should be noted that the UKPDS had very few people on lipid-lowering therapy. Metformin is logical in overweight/obese patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality and is generic.

Adverse Effects. Metformin causes gastrointestinal side effects, including abdominal discomfort, stomach upset, and/or diarrhea in approximately 30% of patients. Anorexia and stomach fullness is likely part of the reason loss of weight is noted with metformin. These side effects are usually mild and can be minimized by slow titration. Gastrointestinal side effects also tend to be transient, lessening in severity over several weeks. If encountered, make sure patients are taking metformin with or right after meals, and reduce the dose to a point at which no gastrointestinal side effects are encountered. Increases in the dose may be tried again in several weeks. Anecdotally, extended-release metformin (Glucophage-XR) may lessen some of the GI side effects. Metallic taste, interference with vitamin B sub 12  absorption, and hypoglycemia during intense exercise has been documented, but are clinically uncommon.

Metformin therapy rarely (3 cases per 100,000 patient-years) causes lactic acidosis. Any disease state that may increase lactic acid production or decrease lactic acid removal may predispose to lactic acidosis. Tissue hypoperfusion, such as that due to congestive heart failure, severe lung disease, hypoxic states, shock, or septicemia, via increased production of lactic acid; and severe liver disease or alcohol, via reduced removal of lactic acid in the liver, all increase the risk of lactic acidosis. The clinical presentation of lactic acidosis is often nonspecific flu-like symptoms, thus the diagnosis is usually made by laboratory confirmation of high lactic acid levels and acidosis. Metformin use in renal insufficiency, defined as a serum creatinine of 1.4 mg/dL in women and 1.5 mg/dL in men or greater, is contraindicated, as it is renally eliminated. Elderly patients, who often have reduced muscle mass, should have their glomerular filtration rate estimated by a 24 hour urine creatinine collection. If the estimated glomerular filtration rate is less than 60 mL/min, metformin should not be given. Though not recommended to be clinically implemented, recent evidence has reported that metformin may not accumulate in moderate to severe renal insufficiency, if a dose of 1,500 mg/day or less is used. Due to the risk of acute renal failure during intravenous dye procedures, metformin therapy should be withheld starting the day of the procedure and resumed in 2 to 3 days, after normal renal function has been documented.

Drug Interactions. Cimetidine competes for renal tubular secretion of metformin and concomitant administration leads to higher metformin serum concentrations. At least one case report of lactic acidosis with metformin therapy implicates cimetidine. Theoretically other cationic drugs may interact, but none have been reported to date.

Dosing and Administration. Immediate-release metformin is usually dosed 500 mg twice a day with the largest meals to minimize gastrointestinal side effects. Metformin may be increased by 500 mg weekly until glycemic goals or 2,500 mg/day is achieved (see Table 83–11). Metformin 850 mg may be dosed daily, and then increased every 1 to 2 weeks to the maximum dose of 850 mg 3 times a day (2,550 mg/day). Approximately 80% of the glycemic-lowering effect may be seen at 1,500 mg, and 2,000 mg/day is the maximal effective dose.

Extended-release metformin can be initiated at 500 mg a day with the evening meal and titrated weekly by 500 mg as tolerated to a single evening dose of 2,000 mg/day. Extended-release metformin 750 mg tablets may be titrated weekly to the maximum dose of 2,250 mg/day, though as stated above, 1,500 mg/day provides the majority of the glycemic-lowering effect. Twice daily to 3 times a day dosing of extended-release metformin may help to minimize gastrointestinal side effects and improve glycemic control.

Thiazolidinediones Pharmacology. Thiazolidinediones are also referred to as TZDs or glitazones. Pioglitazone (Actos) and rosiglitazone (Avandia) are the two currently approved thiazolidinediones for the treatment of type 2 DM (see Table 83–11). Thiazolidinediones work by binding to the peroxisome proliferator activator receptor-γ (PPAR-γ), which are primarily located on fat cells and vascular cells. The concentration of these receptors in the muscle is very low; thus this is unlikely to be the main site of action. Thiazolidinediones enhance insulin sensitivity at muscle, liver, and fat tissues indirectly. Thiazolidinediones cause preadipocytes to differentiate into mature fat cells in subcutaneous fat stores. Small fat cells are more sensitive to insulin and more able to store free fatty acids. The result is a flux of free fatty acids out of the plasma, visceral fat, and liver into subcutaneous fat, a less insulin-resistant storage tissue. Muscle intracellular fat products, which contribute to insulin resistance, also decline. TZDs also effect adipokines, (e.g., angiotensinogen, tissue necrosis factor-α, interleukin 6, plasminogen activator inhibitor 1) which can positively affect insulin sensitivity, endothelial function, and inflammation. Of particular note, adiponectin is reduced with obesity and/or diabetes, but is increased with TZD therapy, which improves endothelial function, insulin sensitivity, and has a potent antiinflammatory effect. Lastly, TZDs appear to improve mitochondrial function through a reduction in free fatty acids. Cyclo-dependent kinase 5 has also recently been purposed as an important activator of PPAR-γ.

Pharmacokinetics. Pioglitazone and rosiglitazone are well absorbed with or without food. Both are highly (>99%) bound to albumin. Pioglitazone is primarily metabolized by CYP2C8, a lesser extent by CYP3A4 (17%), and by hydroxylation/oxygenation. The majority of pioglitazone is eliminated in the feces. Rosiglitazone is metabolized by CYP2C8, and to a lesser extent by CYP2C9, and also by N-demethylation and hydroxylation. Two-thirds is found in urine and one-third in feces. The half-lives of pioglitazone and rosiglitazone are 3 to 7 hours and 3 to 4 hours, respectively. Two active metabolites of pioglitazone with longer half-lives deliver the majority of activity at steady state. Pioglitazone requires no dosage adjustment in moderate to severe renal disease for pharmacokinetic reasons. Interestingly, with pioglitazone the AUC in women is 20% to 60% higher, which is not seen with rosiglitazone, but no dosage adjustment is recommended. Both medications have a duration of antihyperglycemic action of over 24 hours.

Efficacy. Pioglitazone and rosiglitazone, given for about 6 months, reduce HbA sub 1c  values ~1.5% and reduce FPG levels by ~60 to 70 mg/dL at maximal doses. Glycemic-lowering onset is slow, and maximal glycemic-lowering effects may not be seen until 3 to 4 months of therapy. It is important to inform patients of this fact and that they should not stop therapy even if minimal glucose lowering is initially encountered. The efficacy of both drugs is dependent on sufficient insulinemia. If there is insufficient endogenous insulin production (β-cell function) or exogenous insulin delivery via injections, neither will lower glucose concentrations efficiently. Interestingly, patients who are more obese, or who gain weight on
either medication tend to have a larger reduction in HbA<sub>1c</sub> values. Pioglitazone consistently decreases plasma triglyceride levels by 10% to 20%, whereas rosiglitazone tends to have a neutral effect. LDL-C concentrations tend to increase with rosiglitazone 5% to 15%, but do not significantly increase with pioglitazone. Both appear to convert small, dense LDL particles, which have been shown to be highly atherogenic, to large, fluffy LDL particles that are less dense. Large, fluffy LDL particles may be less atherogenic, but any increase in LDL must be of concern. Both drugs increase HDL similarly, up to 3 to 9 mg/dL. Thiazolidinediones also affect several components of the insulin resistance syndrome. PAL-1 levels are decreased, and many other adipocytokines are affected, endothelial function improves, and blood pressure may decrease slightly.

**Microvascular Complications.** Thiazolidinediones reduce HbA<sub>1c</sub> levels, which have been shown to be related to the risk of microvascular complications.

**Macrovascular Complications.** Macrovascular complications with thiazolidinediones are controversial. In PROactive, the prospective pioglitazone clinical trial in macrovascular events, pioglitazone 45 mg was added to standard therapy in patients who had experienced a macrovascular event or had peripheral vascular disease.<sup>57</sup> The two groups were well matched at baseline and the reported average observation time period was about 3 years. The primary endpoint (reduction in death, myocardial infarction, stroke, acute coronary syndrome, coronary revascularization, leg amputation, and leg revascularization) was reduced 10% (P = 0.095). The main secondary endpoint (all-cause mortality, nonfatal myocardial infarction, or stroke) was reduced 16% (P = 0.027). The seemingly dichotomous results relate to the inclusion of leg revascularization as a primary endpoint, which were increased in the pioglitazone group. Reasons for the increase are speculative, but may relate to more testing/inspection due to peripheral edema. Also of note, the pioglitazone group had 209 nonadjudicated admissions for heart failure occur versus 153 in the placebo group (P = 0.007), though fatal heart failure was not increased. Several published meta-analysis of rosiglitazone reported higher myocardial infarction (MI) rates with rosiglitazone, but none have reported a higher risk of mortality. A hazard ratio (HR) of 1.43 (95% confidence interval [CI], 1.03–1.98; P = 0.03) for the risk of an MI with rosiglitazone versus other oral agents was reported.<sup>58</sup> A prospective, multicenter, open-label noninferiority trial in 4,447 patients of rosiglitazone added to background metformin or sulfonylurea versus the active comparator metformin + sulfonylurea was recently reported. Rosiglitazone Evaluated for Cardiovascular Outcomes in Oral Agent Combination Therapy for Type 2 Diabetes [RECORD]). Rosiglitazone was noninferior to the comparator for all CV outcomes except for heart failure. A nonsignificant increase in risk for MI (HR, 1.14; 95% CI, 0.80–1.63) as well as a nonsignificant reduction in stroke (HR, 0.72; 95% CI, 0.49–1.05) was reported. On subset analysis, previous ischemic heart disease trended toward a higher risk (HR, 1.26; CI, 0.95–1.68; P = 0.055). Questions still linger about the study being underpowered and certain subsets of subjects taken o rosiglitazone when given insulin; but RECORD, the only study to look at CVD risk prospectively with rosiglitazone, was neutral.<sup>59</sup>

**Adverse Effects.** Troglitazone, the first thiazolidinedione approved, caused idiosyncratic hepatotoxicity and had 28 deaths from liver failure, which prompted removal from the U.S. market in March 2000. Approximately 1.9% of patients placed on troglitazone had alanine aminotransferase (ALT) levels more than 3 times the upper limit of normal. The incidence, using these criteria for elevated liver enzymes, with pioglitazone (0.25%) and rosiglitazone (0.2%) has been low. No evidence of hepatotoxicity was reported in an analysis of more than 5,000 patients given rosiglitazone or pioglitazone.<sup>60</sup> Several case reports of hepatotoxicity with rosiglitazone or pioglitazone have been reported, but improvement in ALT was consistently noted when the drug was discontinued. Prior to therapy, it is recommended that an ALT be checked, and periodically after at the practitioner’s discretion. Patients with ALT levels >2.5 times the upper limit of normal should not start either medication, and if the ALT is >3 times the upper limit of normal the medication should be discontinued.

Retention of fluid leads to many different possible side effects with rosiglitazone and pioglitazone. The etiology of the fluid retention has not been fully elucidated, but appears to include peripheral vasodilation and/or improved insulin sensitization at the kidney with a resultant increase in renal sodium and water retention. A reduction in plasma hemoglobin (2%–4%), attributed to a 10% increase in plasma volume, may result in a dilutional anemia which does not require treatment. Edema is also commonly (4%–5% in mono- or combination therapy) reported. When a thiazolidinedione is used in combination with insulin, the incidence of edema (~15%) is increased. Thiazolidinediones are contraindicated in patients with New York Heart Association Class III and IV heart failure, and great caution should be exercised when given to patients with Class I and II heart failure or other underlying cardiac disease, as pulmonary edema and heart failure have been reported. Edema tends to be dose related and if not severe, a reduction in the dose as well as use of diuretics, anecdotally hydrochlorothiazide with triamterene, amiloride, or spironolactone instead of loop diuretics, will allow the continuation of therapy in the majority of patients.<sup>65</sup> Rarely, thiazolidinediones have been reported to worsen macular edema of the eye.

Weight gain, which is also dose related, can be seen with both rosiglitazone and pioglitazone. Mechanistically, both fluid retention and fat accumulation play a part in explaining the weight gain. Thiazolidinediones, besides stimulating fat cell differentiation, also reduce leptin levels, which stimulate appetite and food intake. Average weight gain varies, but a 1.5- to 4-kg weight gain is not uncommon. Rarely, a patient will gain large amounts of weight in a short period of time, and this may necessitate discontinuation of therapy. Weight gain positively predicts a larger HbA<sub>1c</sub> reduction, but must be balanced with the well-documented effects of long-term weight gain.

Thiazolidinediones have also been associated with an increased fracture rate in the upper and lower limbs in women and men, though women appear to have a higher risk. These fractures are not osteoporitic in the classic sense, and do not occur in common osteoporosis fracture sites such as spine or hip. Most occur in wrists, forearms, ankles, or feet. Versus comparative diabetes therapy, thiazolidinediones may increase the risk of a fracture by 25%. The underlying pathophysiology is speculative, but may relate

---

**CLINICAL CONTROVERSY**

At a minimum, antihyperglycemic drugs should be neutral on cardiovascular events, because the majority of people with diabetes die from CVD. Both pioglitazone and rosiglitazone, equally, can result in pulmonary edema and/or heart failure, and using them with insulin or in people with preexisting heart failure may increase the incidence. TZD-related congestive heart failure is not associated with a higher risk of mortality. Several meta-analyse have reported an increased risk of MI with the use of rosiglitazone. In the randomized, prospective RECORD trial, rosiglitazone was noninferior to the comparator for all CV outcomes except for heart failure. In contrast, no study has shown an increased risk for MI with pioglitazone, and in PROactive, there was a significant 16% reduction in the combined endpoint of mortality, MI, and stroke. Overall, prospective evidence to date shows TZDs to be neutral on CVD risk except for heart failure, with a potential lowering of CVD risk with pioglitazone.
to thiazolidinediones effect on the pluripotent stem cell and shunting
of new cells to fat instead of osteocytes. It would be prudent to
consider a patient’s risk factors for fractures if a thiazolidinedione
is being considered as antidiabetic therapy.

As a caution, premenopausal anovulatory patients may resume
ovulation on thiazolidinediones. Adequate pregnancy and contra-
ception precautions should be explained to all women capable of
becoming pregnant, as both agents are pregnancy category C.

**Drug Interactions.** Significant drug interactions that can cause
clinical sequelae have not been noted with either medication.
Neither pioglitazone nor rosiglitazone appear to be inhibitors
of insulin secretion, though drugs that are strong inhibitors or inducers of these path-
ways (e.g., gemfibrozil or rifampin) may increase or decrease levels
of active drug significantly.

**Dosing and Administration.** The recommended starting dos-
ages of pioglitazone and of rosiglitazone are 15 to 30 mg once daily
and 2 to 4 mg once daily, respectively. Dosages may be increased
slowly based on therapeutic goals and side effects. The maximum
dose and maximum effective dose of pioglitazone is 45 mg, and
rosiglitazone is 8 mg once daily, though 4 mg twice a day may
reduce HbA1c by 0.2% to 0.3% more versus 8 mg once daily.

**α-Glucosidase Inhibitors Pharmacology.** Currently, there are two α-glucosidase inhibitors available in the United States
acarbose (Precose) and miglitol (Glyset). α-Glucosidase inhibi-
tors competitively inhibit enzymes (maltase, isomaltase, sucrase,
and glucoamylase) in the small intestine, delaying the breakdown
of sucrose and complex carbohydrates. They do not cause any
malabsorption of these nutrients. The net effect from this action is
to reduce the postprandial blood glucose rise.

**Pharmacokinetics.** The mechanism of action of α-glucosidase
inhibitors is limited to the luminal side of the intestine. Some
metabolites of acarbose are systemically absorbed and renally
excreted, whereas the majority of miglitol is absorbed and renally
excreted unchanged.

**Efficacy.** Postprandial glucose concentrations are reduced
(40–50 mg/dL), while fasting glucose levels are relatively unchanged
(−10% reduction). Efficacy on glycemic control is modest (average
reductions in HbA1c of 0.3%–1%), affecting primarily postprandial
glycemic excursions. Thus, patients near target HbA1c levels with
near-normal fasting plasma glucose levels, but high postprandial
levels, may be candidates for therapy.

**Microvascular Complications.** α-Glucosidase inhibitors moder-
ately reduce HbA1c levels, which has been shown to be related to
the risk of microvascular complications.

**Macrovascular Complications.** The STOP-NIDDM study, in
subjects with impaired glucose tolerance, reported a significant reduc-
tion in the risk of cardiovascular events, though the total number of
events were small. No large cardiovascular study confirming these
preliminary results has been done in prediabetes or diabetes patients.

**Adverse Effects.** The gastrointestinal side effects, such as flatu-
ence, bloating, abdominal discomfort, and diarrhea, are very
common and greatly limit the use of α-glucosidase inhibitors.
Mechanistically, these side effects are caused by distal intestinal
degradation of undigested carbohydrate by the microflora, which
results in gas (CO2 and methane) production. Microflora con-
vert the carbohydrate to short-chain fatty acids which are mostly
absorbed, thus there is not a large calorie loss. α-Glucosidase inhibi-
tors should be initiated at a low dose and titrated slowly to reduce
gastrointestinal intolerance. Beano, an α-glucosidase enzyme, may
help to decrease gastrointestinal side effects, but may decrease effi-
cacy slightly, and it is better to decrease carbohydrate or the dose of
the α-glucosidase inhibitor.

If a patient develops hypoglycemia within several hours of ingest-
ing an α-glucosidase inhibitor, oral glucose is advised because the
drug will inhibit the breakdown of more complex sugar molecules.
Milk, with lactose sugar, may be used as an alternative when no glu-
cose is available, as acarbose only slightly (10%) inhibits lactase.

Rarely, elevated serum aminotransferase levels have been
reported with the highest doses of acarbose. It appeared to be
dose and weight related, and is the premise for the weight-based
maximum doses.

**Dosing and Administration.** Dosing for both miglitol and acar-
bose are similar. Initiate with a very low dose (25 mg with one meal
da day); increase very gradually (over several months) to a maximum
of 50 mg 3 times a day for patients ≤60 kg or 100 mg 3 times a day
for patients >60 kg (see Table 83–11). Titration speed should be
varied based on gastrointestinal side effects to the target dose.
Both α-glucosidase inhibitors should be taken with the first bite
of the meal so that drug may be present to inhibit enzyme activity.
Only patients consuming a diet high in complex carbohydrates will
have significant reductions in glucose levels. α-Glucosidase inhibi-
tors are contraindicated in patients with short-bowel syndrome or
inflammatory bowel disease, and neither should be administered
in patients with serum creatinine >2 mg/dL, as this population has
not been studied.

**Dipeptidyl Peptidase 4 Inhibitors (DPP-4 Inhibitors)** Sitagliptin (Januvia) and saxagliptin (Onglyza) are the two DPP-4
inhibitors currently approved in the United States.

**Pharmacology.** DPP-4 inhibitors prolong the half-life of endog-
enously produced GLP-1 and glucose-dependent insulinotopic
polypeptide (GIP) which is normally only minutes. GIP levels are
normal in type 2 DM, and may contribute a minor amount of
insulin secretion but have no effect on glucagon. It has clearly
been shown that GLP-1 levels are deficient in type 2 DM. As
these agents block nearly 100% of the DPP-4 enzyme activity for
at least 12 hours, normal physiologic, nondiabetic GLP-1 levels
are achieved. DPP-4 inhibitors significantly reduce the inap-
propriately elevated glucagon postprandially, though not back to
nondiabetic levels, and improve insulin response to a high glucose
level. Insulin levels tend to be unchanged with DPP-4 inhibitors,
but glucose levels are reduced. This is an improvement in insulin
secretion, as a nondiabetic person would decrease insulin secretion
in response to the lower glucose readings. These drugs do not alter
gastric emptying or have significant satiety effects.

**Pharmacokinetics.** Sitagliptin appears to have rapid absorption,
with a t1/2 of approximately 1.5 hours. Absolute bioavailability after
oral intake is approximately 87%. Only ~40% is bound to plasma
proteins, and the volume of distribution is approximately 200 liters.
The t1/2 of sitagliptin is approximately 12 hours, and 79% of the dose
of sitagliptin is excreted unchanged in the urine by active tubular
secretion, though the organic anion transporter 3 or p-glycoprotein
transport may be involved as well. Sitagliptin exposure is increased
by approximately 2.3–3.8-, and 4.5-fold relative to healthy subjects
for patients with moderate renal insufficiency (creatinine clearance
[Clcr] 30 to <50 mL/min), severe renal insufficiency (Clcr <30 mL/
min), and ESRD (on dialysis), respectively. Though not a safety
or adverse reaction issue, reduction of the dose based on renal
function is appropriate, as only 100% of the enzyme can be inhib-
it, and long-term exposure to higher levels in humans has not
been extensively studied. Pharmacodynamically, DPP-4 inhibition
appeared to mirror directly the plasma concentration of sitagliptin.
Doses of 50 mg produced at least 80% inhibition of DPP-4 enzyme
activity at 12 hours, and 100 mg produced 80% inhibition of DPP-4
enzyme activity at 24 hours. Food had no effect on absorption kinet-
ics of sitagliptin, and hepatic impairment, age, gender, or race had
no effect on the pharmacokinetics.
The \( t_{\text{max}} \) increased about 20 minutes and the AUC increased about 27% when saxagliptin was administered with a high-fat meal, though saxagliptin may be given with or without meals. The oral bioavailability of saxagliptin is approximately 67%. Distribution is similar to the body water compartment. There is negligible protein binding, and one active metabolite, 5-hydroxy saxagliptin, which is half as potent a DPP-4 inhibitor as the parent compound, and contributes to activity. Metabolism is by the CYP3A4/5 system, and strong inhibitors or inducers will have an effect on activity. The half-life of saxagliptin and its active metabolite are 2.5 hours and 3.1 hours, respectively. Approximately 25% of the dose is found in feces representing unabsorbed drug and bile excretion. No accumulation was noted with saxagliptin or its active metabolite. Females have ~25% more exposure to 5-hydroxy saxagliptin, and accumulation was noted with saxagliptin or its active metabolite. Saxagliptin is renally eliminated, and some renal excretion is seen. In moderate \((\text{CL}_{\text{cr}} < 30 \text{ mL/min})\) renal impairment, saxagliptin and its active metabolite exposure are increased 2.1- and 4.5-fold, respectively.

**Efficacy.** The average reduction in HbA\( \text{a1c} \) with sitagliptin or saxagliptin is approximately 0.7% to 1% at maximum dose. The HbA\( \text{a1c} \) decrement is dependent on the baseline value, with a larger reduction being seen with a higher baseline HbA\( \text{a1c} \). As they are well tolerated, adjustment in the dose for adverse effects is unlikely.

**Microvascular and Macrovascular Complications.** HbA\( \text{a1c} \) levels are reduced, which has been related to a reduction in microvascular complications, but no outcome data are available to date.

**Drug–Drug Interactions.** Significant drug–drug interactions with sitagliptin are unlikely. Saxagliptin is metabolized approximately 20% by CYP450 3A4 with some CYP450 2C8 involvement, but is neither an inhibitor nor inducer of any CYP450 enzyme system. Sitagliptin is a p-glycoprotein substrate, but had negligible effects on digoxin and cyclosporine A, increasing the AUC by only 30%.

Saxagliptin is metabolized by CYP3A4/5, and is a substrate for p-glycoprotein substrate, but is neither an inhibitor nor inducer. Rifampin, an inducer, can decrease active levels by 50%. Moderate to strong inhibitors or inducers of CYP3A4/5, such as diltiazem or ketoconazole, can increase the AUC of saxagliptin by approximately 2-fold, with a corresponding decrease in the formation of the active metabolite 5-hydroxy saxagliptin. It is recommended that the dose of saxagliptin be limited to 2.5 mg daily if a stronger inhibitor is used.

**Adverse Effects.** Both drugs are very well tolerated, weight neutral, and do not cause gastrointestinal side effects. Mild hypoglycemia may occur, but in monotherapy or in combination with medication that have a low incidence of hypoglycemia, DPP-4 inhibitors do not increase the risk of hypoglycemia. Headache and nasopharyngitis, potentially related to the drug, may be slightly more common with DPP-4 inhibitors, but no significant increases in peripheral edema, hypertension, or cardiac outcomes have been noted to date.

Uticaria and/or facial edema may be seen in approximately 1% of patients, and discontinuation is warranted. Rare cases of Stevens-Johnson syndrome have been reported.

In regard to long-term safety, DPP-4 enzymes metabolize a wide variety of peptides (PYY, neuropeptide Y, growth hormone-releasing hormone, vasoactive intestinal polypeptide, and others) potentially affecting other regulatory systems. DPP-4 (also known as CD26) plays an important role for T-cell activation and theoretically the inhibition of DPP-4 could be associated with adverse immunologic reactions. Saxagliptin results in a dose-related reduction in absolute lymphocyte count. Approximately 1.5% of patients had a count less than 750 cells/microliter, and discontinuation/rechallenge was confirmed in some patients. The clinical relevance is not known, but if prolonged infection is encountered, it is logical to measure lymphocyte counts and consider discontinuation.

Additionally DPP-8/9 inhibition in animals produced multiple toxicities. Sitagliptin is more selective for DPP-4 than DPP-8/9 (>2,600-fold). Saxagliptin and its active metabolite 5-hydroxy saxagliptin are more specific for DPP-4 than DPP-8 (400- and 950-fold) and DPP-9 (75- and 160-fold), respectively.

**Dosing and Administration** Sitagliptin is dosed orally at 100 mg daily unless renal insufficiency is present. The 50-mg dose is recommended if the creatinine clearance is 30 to less than 50 mL/min, or 25 mg if less than 30 mL/min. Equivalent serum creatinine levels are as follows: sitagliptin 50 mg daily in men, greater than 1.7 to 3.0 mg/dL, women, greater than 1.5 to 2.5 mg/dL; 25 mg daily in men, greater than 3.0 mg/dL, women, greater than 2.5 mg/dL. Saxagliptin is dosed orally 5 mg daily, unless the creatinine clearance is less than 50 mL/min, or strong CYP3A4/5 inhibitors are used, then the recommended daily dose is 2.5 mg. Because of their excellent tolerability profile and a fairly flat dose-response curve, these drugs should be maximally dosed, unless noted above.

**Bile Acid Sequestrants** Currently, the only bile acid sequestrant approved for the treatment of type 2 DM is colesevelam (Welchol).

**Pharmacology.** Colesevelam is a bile acid sequestrant which acts in the intestinal lumen to bind bile acid, decreasing the bile acid pool for reabsorption. Whether colesevelam’s mechanism of action to lower plasma glucose levels is in the intestinal lumen, a systemic effect due to the intestinal lumen effect or some combination of these two is unknown.

**Pharmacokinetics.** Colesevelam is not absorbed from the intestinal lumen, thus there is no absorption, distribution, or metabolism.

**Efficacy.** HbA\( \text{a1c} \) reductions from baseline (~8.0%) were approximately 0.4% when a dose of 3.8 g/day was added to stable metformin, sulfonylureas, or insulin. The fasting plasma glucose was modestly reduced about 5 to 10 mg/dL. Colesevelam may also reduce LDL-C cholesterol. A 12% to 16% reduction in LDL-C was reported with type 2 DM and a baseline LDL-C concentrations of ~105 mg/dL. Triglycerides increased when combined with sulfonylureas or insulin, but not with metformin. Colesevelam is weight neutral. Pediatric patients (10–17 years of age) have been studied for cholesterol reduction, but not for type 2 DM.

**Microvascular Complications.** Bile acid sequestrants modestly reduce HbA\( \text{a1c} \) levels, which have been shown to be related to the risk of microvascular complications.

**Macrovascular Complications.** Though colesevelam lowers plasma glucose and LDL-C, it has not been proven to prevent cardiovascular morbidity or mortality.

**Drug–Drug Interactions.** There are multiple absorption related drug–drug interactions with colesevelam. Tables 83–13, 83–14, and 83–15 summarizes medications that may interact with colesevelam. It is recommended that medications suspected of an interaction should be moved at least 4 hours prior to dosing the colesevelam. Colesevelam has also been implicated in the malabsorption of fat-soluble vitamins (A, E, D, K). In addition to the obvious fat-soluble vitamin supplementation, this may have implications for associated conditions. Other drugs that are very fat soluble such as cyclosporine A, drugs that may be affected by a change in fat-soluble vitamin status such as warfarin and vitamin K, or conditions that may that may be potentially worsened by fat-soluble vitamin status such as some bleeding disorders or dermatologic conditions should be monitored.

**Adverse Effects.** The most common side effects are gastrointestinal. Constipation (11%) and dyspepsia (8%) are more common with colesevelam than placebo. Because of the constipating effects of
Dopamine Agonists

Bromocriptine mesylate (Cycloset) is currently approved for the treatment of type 2 DM, but is not commercially available at the time this chapter was written. In clinical trials, bromocriptine mesylate reduced HbA1c by a modest 0.1% to 0.4% from baseline (HbA1c 8%–9%). Efficacy. In clinical trials, bromocriptine mesylate reduced HbA1c by a modest 0.1% to 0.4% from baseline (HbA1c 8%–9%).

Dose Administration. Dosing for type 2 DM is six 625-mg tablets daily (total dose/day = 3.75 g), which may be split into 3 tablets 2 times a day if desired. A 3.75-g oral suspension packet, dosed daily, or a 1.875-g oral suspension packet dose twice daily is also available. Suspension packets must be diluted in a minimum of one-half to 1 cup of water. Take tablets and suspension with a large amount of water, if possible. All dosage forms should be administered with meals as colesevelam binds to bile released during the meal.

Dopamine Agonists. Bromocriptine mesylate (Cycloset) is currently approved for the treatment of type 2 DM, but is not commercially available at the time this chapter was written. In vertebrates, oscillations in neurotransmitters, including dopamine, can change the response to insulin, and animal and human data indicate that bromocriptine administered in the morning improves insulin sensitivity.

Pharmacology. Bromocriptine is a dopamine agonist, but the exact mechanism of how bromocriptine improves glycemic control is unknown. In vertebrates, oscillations in neurotransmitters, including dopamine, can change the response to insulin, and animal and human data indicate that bromocriptine administered in the morning improves insulin sensitivity.

Pharmacokinetics. Bioavailability is 65% to 95% after an orally administered dose, bioavailability may be increased ~50% if given with a meal. Bromocriptine is highly protein bound, and has a volume of distribution of 61 liters. Only ~7% reaches the systemic circulation due to gastrointestinal-based metabolism and first-pass metabolism. Bromocriptine is extensively metabolized by the CYP3A4 pathway, and the majority (~95%) is excreted in the bile. The half-life is approximately 6 hours. Plasma exposure is increased in females by approximately 18% to 30%, but no dosage adjustment is currently recommended.

Efficacy. In clinical trials, bromocriptine mesylate reduced HbA1c by a modest 0.1% to 0.4% from baseline (HbA1c 8%–9%).

Drug–Drug Interactions. Bromocriptine is extensively metabolized by CYP3A4 and strong inhibitors or inducers may change bromocriptine levels. As bromocriptine is highly protein bound, it may increase the unbound fraction of other highly protein bound drugs. Several drug–drug and potential drug–disease interactions are present including antipsychotics in psychotic disorders as they decrease dopamine activity, atypical antipsychotics, as they may decrease the effectiveness of bromocriptine, and ergot-based therapy for migraines as bromocriptine may increase migraine and ergot related nausea and vomiting. There are case reports of hypertension and tachycardia when administered with sympathomimetic drugs in postpartum women, and bromocriptine should not be given to this group of potential patients. The effectiveness in other disease states where dopamine agonism may be indicated is unknown.

Adverse Effects. Adverse reactions leading to discontinuation occurred in 24% of bromocriptine patients compared to 9% in the placebo comparator group. Nausea, rhinitis, headache, asthenia, dizziness, constipation, and sinusitis all occurred in over 10% of subjects. Nausea occurred in 25% to 35% of patients, and vomiting, which tended to be more common in women, occurred in 5% to 6% of patients. Nausea, vomiting, fatigue, headache, and dizziness were common adverse events during the titration phase of phase 3 studies, and only 70% of completors could be titrated to the maximum dose. Orthostatic hypotension or syncope occurred in 2.2% and 1.4%, and 0.6% and 0.8% in the bromocriptine and placebo groups, respectively. No predisposing factors were identified, but caution should be exercised in patients with low, normal blood pressure. Somnolence was reported in 4.3% of patients on bromocriptine, compared with 1.3% in the placebo, and response to the drug should be ascertained prior to operating machinery or combining with other sedating medications. Psychiatric disorders including hallucinations and pathological gambling have been reported with other forms of bromocriptine, but were not seen in phase III trials.

Dosing and Administration. Bromocriptine is dosed with 0.8-mg tablets administered within 2 hours of waking from sleep daily. From 0.8 mg daily, the dose may be increased weekly based on response by 0.8-mg tablet increments, to a maximum of 4.8 mg daily (0.8 mg x 6 tablets, though it is unclear if another commercial dose could be made available). The minimal effective dose is 1.6 mg daily.

Microvascular and Macrovacular Complications. It is unclear what effect, if any, bromocriptine may have on outcomes, though no increase in cardiovascular event signal was detected from data presented to the FDA.

POTENTIAL FUTURE MEDICATIONS

Many medications for the treatment of diabetes are currently in late-phase development. No guarantee of FDA approval is given for any agent in development.
Endocrinologic Disorders

Exenatide Long-Acting-Release (Bydureon)

A once-weekly, long-acting injection preparation of the current twice-daily exenatide formulation is being developed. Exenatide is embedded in small beads of material similar to absorbable suture material. This allows for the embedded exenatide to be released over 1 week. Data out to 1 year has shown better FPG and HbA\textsubscript{1c} lowering than the current twice daily exenatide. Safety and side effects, with slightly less nausea with the weekly preparation, appears similar to twice daily exenatide.

Other Incretin Class Medications

Several other DPP-4 inhibitors may be approved, including aloglipatin, dutogliptin, and linagliptin. There will likely be many DPP-4 inhibitors on the market soon. Taspoglutide, a once-weekly human analog GLP-1 agonist may also be approved in the next several years. Taspoglutide dosing is speculative, but will likely be 20 to 30 mg weekly.

Selective Sodium-dependent Glucose Cotransporter-2 Inhibitors (SGLT-2 Inhibitors)

SGLT-2 inhibitors work in the kidney to block the reabsorption of some glucose. Normally, all glucose is reabsorbed back into the systemic circulation from the kidney at normal glucose levels; about 10% through the SGLT-1 receptor, and 90% through the SGLT-2 receptor. Early data has shown approximately 50 to 80 grams of glucose per day may be allowed to pass into the urine with SGLT-2 inhibition. This lowers systemic glucose and allows weight loss. Glucose levels may be lowered in both type 1 and type 2 DM by this mechanism of action. Safety data has shown a slightly higher rate of genitourinary yeast infections to date. SGLT-1 is involved with glucose absorption in the gut, and selectivity is important, as inhibition of SGLT-1 may cause gastrointestinal toxicity. Dapagliflozin is currently the farthest in development, but several are being developed.

Diabetes Control and Complications Trial

Much of the last century in diabetes care was dominated by the debate over whether glycemic control actually was causative in complications of DM. Animal studies and some human studies suggested that the worse the glycemia the greater the risk of complications. But “the glucose hypothesis” was not ultimately accepted as proven until the publication of the DCCT in 1993. In this study, 1,441 patients with type 1 DM were divided into two groups: those without complications (726 subjects, primary prevention), and those with early microvascular complications (715 subjects, secondary prevention). These two groups were then again divided into two groups, one randomized to receive conventional therapy (one or two shots of insulin daily and infrequent SMBG with no attempt to change therapy based on home blood glucose readings), and the other to receive intensive therapy (3+ injections of insulin daily or insulin pump, with frequent SMBG and alteration of insulin therapy based on SMBG results, plus frequent contact with a health professional). After 6.5 years, mean follow-up with a difference in HbA\textsubscript{1c} between the two groups being \( \approx 2\% \) (\( \approx 9\% \) vs \( \approx 7\% \)), retinopathy was decreased by 76% in the primary prevention cohort, with retinopathy progression reduced 54% in the secondary prevention group. Neuropathy was decreased by 60% in both groups combined. Microalbuminuria was decreased 39%, while macroproteinuria was reduced 54% with intensive therapy. Hypoglycemia was more common and weight gain greater with intensive therapy. A nonstatistically significant reduction in coronary events was seen in the intensively treated group as compared with the conventional group. The DCCT revolutionized therapy of DM, demanding that stricter glycemic control be the goal.

United Kingdom Prospective Diabetes Study

The UKPDS was a landmark study for the care of patients with type 2 DM, confirming the importance of glycemic control for reducing the risk of microvascular complications. More than 5,000 patients with newly diagnosed type 2 DM were entered into the study. Patients were followed for an average of 10 years. The major portion of the study assessed “conventional therapy” (no drug therapy unless the patient was symptomatic or had FPG \( > 270 \text{ mg/dL} \)), versus intensive therapy starting with either sulfonylureas or insulin, aimed at keeping the fasting plasma glucose \( < 108 \text{ mg/dL} \). A subset of obese patients was studied using metformin as the primary therapeutic agent.

CLINICAL CONTROVERSY

Significant findings from the study include the following:

- Microvascular complications (predominantly the need for laser photocoagulation on retinal lesions) are reduced by 25% when median HbA\textsubscript{1c} is 7% as compared with 7.9%.
- A continuous relationship exists between glycemia and microvascular complications, with a 35% reduction in risk for each 1% decrement in HbA\textsubscript{1c}. No glycemic threshold for microvascular disease exists.
- Glycemic control has minimal effect on macrovascular disease risk. Excess macrovascular risk appears to be related to conventional risk factors such as dyslipidemia and hypertension.
- Sulfonylureas and insulin therapy do not increase macrovascular disease risk.
- Metformin reduces macrovascular risk in obese patients.
- Vigorous blood pressure control reduces microvascular and macrovascular events. There was no evidence for a threshold systolic blood pressure above 130 mm Hg for protection against complications. -Blockers and ACE inhibitors appear to be equally efficacious.

Long-Term Follow-Up of DCCT (EDIC) and UKPDS

At the conclusion of the DCCT and UKPDS trials, willing subjects continued to be followed over time to ascertain micro- and macrovascular outcomes. In the follow-up of the DCCT, called the Epidemiology of Diabetes Interventions and Complications (EDIC), several important points have been discovered. First, HbA\textsubscript{1c} levels between conventional and intensive groups converged to a HbA\textsubscript{1c} of...
ACCORD, ADVANCE, and VADT

The Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease (ADVANCE), and Veterans Affairs Diabetes Trial (VADT) were three trials that reported on the effects of glycemic control and macrovascular disease risk.

ACCORD randomized 10,251 high CVD risk subjects (CVD event or significant risk) with type 2 DM to intensive glycemic control (goal HbA_1c <6%) or standard glycemic control (HbA_1c 7.0%–7.9%). Multiple oral agents and/or insulin were allowed to achieve glycemic goals. Baseline HbA_1c level was 8.1%, and the intensive glycemic group achieved a HbA_1c of 6.4%, whereas standard glycemic control achieved a HbA_1c of 7.5% when the study stopped after a mean follow-up period of 3.5 years. The study was stopped after an interim analysis reported an increase rate of mortality in the intensive arm (1.41 vs 1.14%/year; HR, 1.22; 95% CI, 1.01–1.46). Interestingly, the primary endpoint (myocardial, stroke, or cardiovascular death) was trending down due to a lower risk of nonfatal MI in the intensive therapy group. In addition, on subset analysis, individuals with a baseline HbA_1c <8.0% or no previous CVD had a significant reduction in the primary outcome. Increased mortality could not be associated with a specific medication, hypoglycemia (higher in intensive group), lipid levels, or weight gain, though substantially increased in the intensive group. The dichotomous results have been hard to explain, though the ACCORD investigators reported that in the intensive group, it was subjects who could not attain intensive glycemic control goals who were at higher risk, not subjects who did achieve the goal. A 20% higher risk of death for each 1% above a HbA_1c of 6% was reported.

ADVANCE randomized 11,140 subjects to intensive (≤6.5% HbA_1c) or standard therapy (investigator-driven goals). Extended-release gliclizide, a sulfonylurea available outside of the United States, was used as first-line therapy in the intensive group versus no gliclizide in the standard therapy group, though multiple other agents were needed in both groups. A baseline HbA_1c was only 7.5%, and at the end of therapy, the intensive group versus standard group HbA_1c was ~6.5% versus ~7.2%. ADVANCE reported a significant reduction in renal events, including new or worsening nephropathy (HR, 0.79; 95% CI, 0.66–0.93), but no difference in major macrovascular events (HR, 0.94; 95% CI, 0.84–1.06) with intensive versus standard therapy.

VADT randomized 1,791 subjects to intensive glycemic control (HbA_1c goal <6.0%, and action required of >6.5%) versus nonintensive glycemic control (investigator determined). At entry, the HbA_1c was the highest of the three trials (9.4%). Multiple medications including insulin were used to achieve glycemic control. The intensive group achieved a HbA_1c of 6.9% versus 8.5% in the investigator determined group. The primary endpoint of nonfatal MI, nonfatal stroke, CVD death, hospitalization for heart failure, and revascularization was not significantly different (HR, 0.88; 95% CI, 0.74–1.05) and mortality was unchanged.

These three trials should be viewed as confirmatory that short term (3–5 years) of intensive glycemic control do not positively affect the risk of macrovascular risk in type 2 DM. ACCORD reported that a subset of subjects that could not achieve intensive glycemic control may be at higher risk of death, but identifying these patients and implementing this recommendation into clinical practice may prove to be challenging. As previously mentioned in the EDIC and follow-up of the UKPDS, reduction of macrovascular events from improved glycemic control may take over a decade to come to fruition.

### THERAPEUTICS

Knowledge of the patient’s quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations and other injectables, and pharmacology of oral and antidiabetic agents for type 2 DM are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.

#### Type 1 Diabetes Mellitus

The choice of therapy for type 1 DM is simple: all patients need insulin. However, how that insulin is delivered to the patient is a matter of considerable practice difference among patients and clinicians. Historically, after the discovery of insulin by Banting and Best in 1921, frequent injections of regular insulin (initially the only insulin available) were given. Modifications of insulin led to longer-acting insulin suspensions and the use by many patients of one or two shots of longer-acting insulin each day. Because self-monitored blood glucose and HbA_1c testing were not available at that time, patients and practitioners had no idea how well their patients’ blood glucose concentrations were controlled, other than a vague sense from an indirect method, measurement of glucose in the urine. While the renal threshold for glucose is relatively predictable in young healthy subjects, it is highly variable in older patients and patients with renal disease. The advent of SMBG and HbA_1c testing in the 1980s revolutionized the care of diabetes, enabling patients and practitioners to directly access blood glucose for assessment, and enabling the patient to make instantaneous changes in the insulin regimen if need be. Modern diabetes management would be impossible without these two tools.

Contemporary management of type 1 DM attempts to match carbohydrate intake with glucose-lowering processes, most commonly insulin, as well as with exercise. Attempts are made to allow the patient to live as normal a life as possible. Understanding the principles of glucose input and glucose egress from the blood will allow the practitioner and the patient great latitude in the management of patients with type 1 DM.

Simplistically speaking, one can break down normal insulin secretion into a relatively constant background level of insulin (“basal”) for the fasting and postabsorptive period, and prandial spikes of insulin after eating (“bolus”) (Fig. 83–8). Insulin sensitivity and insulin secretion are not constant throughout the day, rendering the basal concept inaccurate. However, in most clinical situations, this approach provides a useful paradigm for understanding and applying insulin treatment for type 1 DM. The other basic principle to consider is that the timing of insulin onset, peak, and duration of effect must match meal patterns and exercise schedules to achieve near-normal blood glucose values throughout the day.

Historically, complexity of insulin regimens has usually been related to the number of injections of insulin administered per
day. This is a reasonable classification. Clearly one injection of any insulin preparation daily will in no way mimic normal physiology, and therefore is unacceptable. Similarly, two injections of any insulin daily will fail to replicate normal insulin release patterns. Injection regimens that begin to approximate physiologic insulin release start with “split-mixed” injections of a morning dose of an intermediate acting insulin such as neutral protamine Hagedorn (NPH) and a “bolus” rapid-acting insulin or regular insulin before breakfast, and again before the evening meal. The presumption is made that the morning intermediate-acting insulin gives basal insulin for the day and covers the midday meal, the morning bolus insulin covers breakfast, the evening intermediate-acting insulin gives basal insulin for the rest of the day, and the evening bolus insulin covers the evening meal. If patients are very compulsive about consistency of timing of their injections and meals and intake of carbohydrate, such a strategy may be successful. However, most patients are not sufficiently predictable in their schedule and food intake to allow “tight” glucose control with such an approach.

The first modification that is frequently made to such a regimen is the movement of the evening NPH to bedtime (now three total injections per day) because the fasting glucose in the morning is too high. This approach improves glycemic control and reduces hypoglycemia, sufficiently intensifying the insulin therapy for some patients. However, many patients need a more intense approach that also allows greater flexibility in their lifestyle.

The basal-bolus concept is an attempt to replicate normal insulin physiology with a combination of intermediate- or long-acting insulin to give the basal component, and rapid-acting insulin to give the bolus component. Various strategies have been used for the former, including once- or twice-daily NPH or detemir, or once-daily insulin glargine. Most type 1 DM patients require two shots of all of the above insulins except insulin glargine. Insulin glargine or insulin detemir is a feasible basal insulin supplement for most patients with type 1 DM. The bolus insulin component is given before meals with regular insulin, insulin lispro, insulin aspart, or insulin glulisine. The rapid onset of action and short time course of rapid-acting insulin analogs more closely replicate normal physiology. This approach allows the patient to vary the amount of insulin injected, depending on the preprandial SMBG level, the anticipated activity (upcoming exercise may reduce insulin requirement), and anticipated carbohydrate intake. Most patients will have a prescribed dose of insulin preprandially that they vary by use of an “adjusted scale insulin” or “correction factor” to normalize a high plasma glucose reading in addition to the amount for the anticipated carbohydrate intake. A starting or empiric “correction factor” can be calculated to provide an approximate plasma glucose lowering (mg/dL) effect of 1 unit of short-acting insulin. Take 1,500 divided by the total daily insulin dose the patient currently uses. For rapid-acting insulins, some experts use 1,700 to 1,800 to account for the rapid reduction in glucose after injection. For example, if a patient is taking 45 units of basal insulin and 10 units of rapid-acting insulin at each of three meals, the total daily insulin dose equals 75 units. 1,500 divided by 75 is 20, thus each unit of insulin will lower the plasma glucose approximately 20 mg/dL. Follow-up SMBG data should be implemented to individualize the correction factor. Carbohydrate counting is a very effective tool for determining the amount of insulin to be injected preprandially. Although general algorithms for carbohydrate counting give rough guidelines, each patient will have to adjust the prescribed preprandial insulin dosage based on their response to different food items. An empiric estimate of how much carbohydrate (grams) 1 unit of rapid-acting insulin will cover is to take 500 divided by the total daily dose of insulin. If we add to the example above with a total daily insulin dose of 75 units, we would take 500 divided by 75, we find that empirically, 1 unit of rapid-acting insulin will cover approximately 7 g of carbohydrate. Follow-up SMBG data should be implemented to individualize this ratio.

In type 1 DM, approximately 50% of insulin replacement should be basal insulin, and the other 50% bolus insulin, split among the meals. If the patient’s ratio is not near this recommendation, a reassessment of the regimen should be implemented. Empirically, patients may be begun on ≈0.6 units/kg/ day with basal insulin 50% of total dose and prandial insulin 20% of total dose prebreakfast, 15% prelunch, and 15% presupper. Type 1 DM patients generally require between 0.5 and 1 unit/kg/ day. The need for significantly higher amounts of insulin suggests the presence of insulin antibodies or insulin resistance (coexistent endocrinopathy or type 2 DM).

Obviously, insulin pump therapy (continuous subcutaneous insulin infusion [CSII], generally using a rapid-acting analog insulin) is the most sophisticated form of basal bolus insulin delivery system. CSII may be slightly more efficacious in achieving good glycemic control than multiple-dose insulin injections in a motivated patient. Extensive discussion of this mode of therapy is beyond the scope of this text. Nevertheless, the basic principles for implementation are the same. The one advantage of pump therapy is that the
basal insulin dose may be varied, consistent with changes in insulin requirements throughout the day. In selected patients, this feature will allow greater glycemic control with CSII. However, insulin pumps require even greater attention to detail and frequency of SMBG than four injections daily. In appropriately selected patients willing to pay sufficient attention to detail of SMBG and insulin administration, CSII can be a very useful form of therapy. CSII is a tool for diabetes control, and if the patient is not well controlled or unwilling to actively control the diabetes on injections, it is unlikely that the patient will have superior control on a pump.

Intensive therapy (basal bolus) to all adult patients with type 1 DM at the time of diagnosis is recommended to reinforce the importance of glycemic control from the outset rather than change strategies over time after lack of control. Occasional patients with an extended honeymoon period may need less intense therapy initially, but should be converted to basal bolus therapy at the onset of glycemic lability. For patients insisting on two injections daily, intermediate-acting insulin and a rapid-acting insulin or regular insulin (starting at 0.6 units/kg with two-thirds in the morning, two-thirds of the morning dose as intermediate-acting insulin, and one-half of evening dose as intermediate-acting insulin) may be sufficient. Regardless of the regimen chosen, gross adjustments in the total insulin dose can be made based on HbA1c measurements and symptoms such as polyuria, polydipsia, and weight gain or loss. Finer insulin adjustments can be determined on the basis of the results of frequent SMBG.

All patients receiving insulin should have extensive education in the recognition and treatment of hypoglycemia. Questioning about the recognition of hypoglycemia is warranted at each patient visit. Documentation of frequency of hypoglycemia, particularly that requiring assistance of another person, visit to an emergent or urgent care facility, or hospitalization, should be recorded. In type 1 DM, the development of hypoglycemia unawareness is common. It may result from progression of disease with autonomic neuropathy. Loss of adrenergic warning signs in such a situation is a relative contraindication to intensive insulin therapy. More commonly, type 1 DM patients have loss of warning signs because of a presumed lower set point for release of counterregulatory hormones as a result of frequent episodes of hypoglycemia (“hypoglycemia begets hypoglycemia”). In such situations, more normal hypoglycemia awareness may be restored by reduction or redistribution of the insulin dose to eliminate significant hypoglycemic episodes. Short-term treatment with theophylline will improve hypoglycemia awareness. Other interventions that may help include coffee consumption or sympathomimetics. These therapies, other than possibly coffee, should not routinely be employed, but may be considered in refractory cases.

Children and pubescent adolescents, glycemic goals should be tempered with the risks of hypoglycemia. Table 83–7 lists glycemic goals for different age groups of type 1 DM patients. Therefore it is not unreasonable to use less intense management (two shots per day, premixed insulin) until the patient is postpubertal, if age-specific goals can be maintained. Occasionally, patients have antibodies to injected insulin, but the significance of the antibodies is usually minimal. Human insulin therapy has not totally eliminated insulin allergies, although most patients have a local reaction that will dissipate over time. If mild reactions at the site of injection occur, assess the insulin injected. Many times the patient injects cold insulin, which causes vasodilation around the injection site. Anecdotally, a different source could be tried as well (yeast based if on E. coli based, and vice versa). If the allergic reaction does not improve or is systemic, insulin desensitization can be carried out. Protocols for desensitization are available from major insulin manufacturers. While more common in the animal insulin era, lipohypertrophy is still seen in some patients with long-standing type 1 DM. Such patients give their insulin injections in the same site to minimize discomfort. Because insulin absorption from an area of lipohypertrophy is unpredictable, avoidance of injections into these areas is mandatory.

Several common errors can occur in the therapy of patients with type 1 DM, causing erratic glucose fluctuations:

- Failure to take into account peaks of insulin action when using a peaking insulin and planning meals and/or activity. Eating should be planned around the peaks of the insulin.
- Random rotation of insulin injection sites. There is sufficient variability of insulin absorption from site to site that this practice alone may cause wide glucose swings. The most consistent absorption of insulin is from the abdominal wall. We try to get our patients to take all their injections in the abdomen. If the patient is unable or unwilling to follow this advice, then systematic site rotation is the next preferable option. The patient always gives the insulin injection in the same region of the body the same time of the day each day. For instance, the arms are always used every morning. Needless to say, the patient should not inject in a limb and then go out and exercise that limb, increasing blood flow and insulin absorption.
- Overinsulization is a very common problem. The answer to all high blood glucose is not necessarily more insulin, as the patient may be insulinopenic, or may be “rebounding” from a previous low glucose and treating it with excessive amounts of carbohydrate. Fastidious SMBG, particularly during the night (or selected use of continuous glucose monitoring) will help sort this out. Also, practitioners sometimes do not adequately differentiate type 1 DM from type 2 DM when using insulin. Patients with type 1 DM are insulinopenic but have normal insulin sensitivity. Patients with type 2 DM have varying degrees of insulin resistance. Therefore, a 1 unit change in the dose of insulin for a patient with type 1 DM may have a dramatic effect on glucose concentrations, whereas in some patients with type 2 DM 10 to 20 times that amount of insulin may have little effect on glucose. Large changes in insulin dose in patients with type 1 DM are not usually indicated unless the patient’s blood glucose control is very poor. Widely erratic SMBG results and/or weight gain often suggest overinsulization.
- When in doubt, always double check the patient’s technique for insulin dosing, insulin injection, and SMBG. Sometimes the simplest of errors results in miserable glycemic control.

Pramlintide in type 1 DM patients who continue to have erratic postprandial control despite implementation of the above strategies may be appropriate. It is imperative at initiation of therapy with pramlintide that each dose of prandial insulin (rapid-acting analog or regular insulin) be reduced by 30% to 50%, or severe hypoglycemic reactions may occur. Pramlintide should be judiciously titrated based on gastrointestinal adverse effects and postprandial glycemic goals. Anecdotally, due to delayed gastric emptying, injecting pramlintide prior to the meal and the rapid acting insulin after the meal may better match the appearance of the food with the postprandial increase in glucose. As pramlintide is not recommended for mixing, you are adding an additional prandial injection at each meal. A patient that is cognizant of the hypoglycemic risk, gastrointestinal side effects, and effective strategies to reduce both issues is needed.

Islet cell and whole pancreas transplantation are occasionally used in patients who require immunosuppressive therapy for other reasons, such as renal transplants. There has been considerable interest in islet cell transplantation since investigators in Edmonton reported success without using glucocorticoids as
immunosuppressive agents. Some of these patients are able to stop insulin, though many require insulin secretion support from sulfonylureas or GLP-1 agonists.

**Type 2 Diabetes Mellitus**

Pharmacotherapy for type 2 DM has changed dramatically in the last few years with the addition of several new drug classes and recommendations to achieve more stringent glycemic control. Symptomatic patients may initially require treatment with insulin or combination oral therapy to reduce glucose toxicity (which may reduce β-cell insulin secretion and worsen insulin resistance). Patients with HbA1c ≈7% or less are usually treated with therapeutic lifestyle measures and an agent which will not cause hypoglycemia. Those with HbA1c >7% but <8.5% could be initially treated with single oral agents, or low dose combinations. Patients with higher initial HbA1c may benefit from initial therapy with two oral agents, or even insulin.

Depending on patient motivation and adherence to therapeutic lifestyle changes, most patients with HbA1c greater than 9% to 10% will likely require therapy with two or more oral agents to reach glycemic goals. Treatment of type 2 DM often necessitates use of multiple therapeutic agents (combination therapy), to obtain glycemic goals.

The best initial oral therapy for patients with type 2 DM is widely debated. Based on the results of the UKPDS and safety record, obese patients (>120% ideal body weight) without contraindications should be started on metformin titrated to ≈2,000 mg/day. Near-normal weight patients may be better treated with insulin secretagogues, though metformin will work in this population. Metformin is the only oral antihyperglycemic agent to ever report a reduction in total mortality. Despite this, long-term durability of HbA1c reduction, due to the inability to stop progressive β-cell failure, is suboptimal with metformin, and patients over several years will often need additional therapy. An insulin secretagogue, such as a sulfonylurea, is often added second, though it has clearly been shown that sulfonylureas do not produce durable HbA1c reductions. Better choices to sustain HbA1c reductions would be a TZD or GLP-1 agonist. Goal-oriented therapy is what we should strive for, meaning the intervention should be in relation to the distance from the goal. When initial therapy is no longer keeping the patient at goal, if the HbA1c is close to goal, one additional agent may be appropriate. If >1% to 1.5% above goal, it is unlikely any one oral agent will result in reaching the glycemic goal, and multiple oral agents or insulin therapy may be appropriate. Thiazolidinediones may be substituted in situations in which a patient is intolerant of, or has a contraindication to, metformin as an insulin sensitizer, understanding that thiazolidinediones should be used with caution in heart failure. Figure 83–9 is an algorithm developed by the Texas Diabetes Council for glycemic control. No algorithm can substitute for good clinical judgement, and algorithms for glycemic control start with the premise that the clinician will identify medication contraindications, adverse reactions, and comorbidities that may be advantageous or harmful if the medication was taken.

---

### Glycemic control algorithm for type 2 diabetes mellitus in children and adults

**Glycemic Goals**
- Individualize goal based on patient risk factors
- **A1c < 6%**
- **PP ≤ 110 mg/dL**
- **2h PP ≤ 130 mg/dL**

**Initial Intervention**
1. **Diabetes education and**
2. **SMBG**
3. **Medical nutrition, weight control, exercise**
4. **Dual therapy or consider monotherapy if A1c < 6.5%**

**Options for Dual/combination therapy**
- **Metformin**
- **Metformin or TZD**
- **Metformin + TZD or SU**
- **Metformin + TZD, AGI, SU**
- **Add additional oral agent or exenatide if A1c less than 1% above goal otherwise add insulin as third agent**

**Abbreviations**
- AGI: Alpha-glucosidase inhibitors
- CAD: Coronary artery disease
- DPP-4: Dipeptidyl peptidase-4 inhibitor
- IHD: Ischemic heart disease
- PP: Postprandial
- SMBG: Self-monitored blood glucose
- SU: Sulfonylurea
- TZD: Thiazolidinedione

**Footnotes:**
2. If initial presentation is hyperglycemia PLUS weight loss, use insulin, with or without oral agents, as the initial intervention (see Insulin Algorithm). Other agents may be introduced as glycemic control improves.
3. These interventions should be maintained lifelong (see Medical nutrition, weight loss, and exercise algorithms).
4. Consider stopping/reducing dose of SU as a component of therapy due to risk of hypoglycemia as A1c approaches goal.
5. Metformin is the only FDA-approved oral antidiabetic agent in children (≥ age 10); other agents may be used at the discretion of the clinician.
6. If a SU is selected, low dose glipizide ER or glimepiride are recommended because they have a lower incidence of hypoglycemia than glyburide.
7. DPP-4 inhibitor should not be used in combination with exenatide.

**FIGURE 83–9.** Glycemic control algorithm for type 2 DM in children and adults. See [www.texasdiabetescouncil.org](http://www.texasdiabetescouncil.org) for current algorithms. (Reprinted with permission from the Texas Diabetes Council.)
We should also treat type 2 DM by matching therapy to the suspected underlying problem. Consider some simple questions to guide therapy: (1) How long has the patient had diabetes? The longer a patient has had diabetes, the more insulinopenic they likely are and the more likely that insulin therapy will be needed; (2) Fasting, postprandial, or both plasma glucose issue? Some drugs address postprandial better, whereas some address FPG better; (3) How far do we have to go to goal and what is the goal? Each oral agent has limits on HbA\(_1c\) reduction, and the reduction is baseline HbA\(_1c\) dependent; (4) Adverse effect profile? Contraindications, hypoglycemia potential, and tolerability are based on the current status of the patient; (5) Comorbidities? CVD, dementia, life expectancy, depression, osteoporosis, and other conditions where select medications may be poor choices and additionally those comorbidities may drive our HbA\(_1c\) goal. Based on the ADVANCE, ACCORD, and VADT trials, a HbA\(_1c\) goal may now be above 7% if certain comorbidities are present. See Figure 83–10 for HbA\(_1c\) individualization based on comorbidities from the Texas Diabetes Council. Drugs such as metformin, TZDs, sulfonylureas, repaglinide, liraglutide, intermediate-acting insulins given at bedtime, and basal insulins control fasting plasma glucose more effectively. Exenatide, DPP-4 inhibitors, α-glucosidase inhibitors, nateglinide, and regular and rapid acting insulin better control postprandial glucose excursions. We can also guide therapy based on the risk of hypoglycemia. Metformin, TZDs, liraglutide, exenatide, DPP-4 inhibitors and α-glucosidase inhibitors have a low risk of hypoglycemia. Combining these agents will allow aggressive targeting of near-normal HbA\(_1c\) levels while minimizing hypoglycemia and weight gain. Combining these agents early in the diagnosis of type 2 DM is logical to potentially realize the micro- and macrovascular reduction seen in the long-term follow-up of UKPDS. 

Preserving β-cell function, thus arresting the progressive nature of type 2 DM, could be paradigm changing, but to date medications have only shown to slow, not arrest progression. In the UKPDS, insulin, metformin, or sulfonylureas did not halt β-cell failure. Thiazolidinediones and GLP-1 agonists (open label exenatide has shown durable HbA\(_1c\) reduction to 3 years and liraglutide to 2 years) may potentially slow β-cell failure.\(^{65,86}\) It appears unlikely any one drug class will arrest β-cell failure. Combination therapy with TZDs and GLP-1 agonists is logical as TZDs reduce apoptosis of β cells and GLP-1 agonists augment pancreatic function through insulin secretion in a glucose dependent manner and reduction of inappropriate glucagon, but long-term data is lacking. β-cell function is heavily damaged by the time type 2 DM is diagnosed, and it is possible that β-cell failure is inevitable by type 2 DM diagnosis. HbA\(_1c\) reduction is dependent on baseline values, with higher reductions seen with higher values, but again, therapy should be goal oriented. Triple therapy is often with metformin, a sulfonylurea, and a TZD or DPP-4 inhibitor, but, a good alternative is to use metformin, a TZD, and a GLP-1 agonist, which can lower glucose levels and increase satiety, reducing the weight gain potential of a TZD, and still has a low risk of hypoglycemia. If the HbA\(_1c\) is >8.5% to 9% on multiple therapies, insulin therapy should be considered. Sulfonylureas are often stopped when insulin is added and insulin sensitizers continued. This may be beneficial to decrease hypoglycemia, but continuing the sulfonylurea is permissible until multiple daily injections are started, at which time it should definitely be discontinued.

Virtually all patients with type 2 DM ultimately become relatively insulinopenic and will require insulin therapy. Insulin therapy for type 2 DM has changed dramatically in the last few years. Specifically, patients are often “transitioned” to insulin by using a bedtime injection of an intermediate- or long-acting insulin, and using oral agents primarily for control during the day.\(^{87,88}\)
The largest meal of the day for a total of two injections. If this is unsuccessful, a bolus injection can be given with the second largest meal of the day, for a total of three injections. After this, the standard basal-bolus model is followed. Alternatively, patients may be switched to split mix insulin such as 70/30 mix insulin, Humalog Mix 75/25 or Novolog Mix 70/30. These are often given twice daily before the first and third meal (see 1 DM for longer explanation) but if inadequate control is seen, a third dose of mix insulin may be given with the third meal of the day. This allows for better mealtime coverage, but can also increase the risk of hypoglycemia. Use of exenatide or pramlintide for prandial coverage can be considered. Exenatide should be injected twice before meals, whereas pramlintide can be given before each meal. Concerns and problems with insulin administration as addressed in the section on type 1 DM generally relate to the therapy of type 2 DM. However, patients with type 2 DM rarely have hypoglycemia unawareness. Also, the variability of insulin resistance means that insulin doses may range from 0.7 to 2.5 units/kg or more. Figure 83-11 is an algorithm for insulin therapy options in type 2 diabetes developed by the Texas Diabetes Council. This algorithm gives most options for insulin therapy, but the choice of regimen should be individualized based on the discussion with the patient.

The availability of short-acting insulin secretagogues, rapid-acting insulin analogs, exenatide, DPP-4 inhibitors, and α-glucosidase inhibitors, all of which target postprandial glyceremia, has reminded practitioners that glycemic control is a function of fasting and preprandial glyceremia and postprandial glyceremic excursions. Therefore, postprandial glucose measurements may need more emphasis if the HbA1c is near the glycemic goal. Currently, it remains controversial whether targeting after-meal glucose excursions will have more of an effect on complications risk than...
more conventional strategies. Importantly, postprandial excursions proportionally contribute more than the FPG to the HbA1c, percentage when the HbA1c nears goals, and thus will need to be targeted for optimal glycemic control in many patients. Most evidence is mostly in epidemiologic studies with post-glucose challenge glucose measurements in diabetes and nondiabetes subjects, not in prospective studies.81

**SPECIAL POPULATIONS**

**Children and Adolescents with Type 2 DM**

Type 2 DM is increasing in adolescence.10 Obesity and physical inactivity seem to be particular culprits in the pathogenesis of this disease. Given the many years the patient will have to live with diabetes, and recent evidence that the timeline for complications may mimic that of older adults, extraordinary efforts should be expended on lifestyle modification measures in an attempt to normalize glucose levels. Failing that strategy, the only labeled oral agent for use in children (10–16 years of age) is metformin, though sulfonylureas are also commonly used in therapy. Thiazolidinediones have not been studied in children, but studies to ascertain safety and efficacy are currently under way. Exenatide, as it potentially helps the child to lose weight, is also increasing, but the long-term effects of this therapeutic modality are unknown. Exenatide has been submitted to the FDA for approval in children. In adolescent females, the possibility of future pregnancy should be considered in the prescription of any drug regimen.

**Elderly Patients with DM**

Elderly patients with newly diagnosed DM (almost always type 2 DM) present a different therapeutic challenge. Consideration of the risks of hypoglycemia in this population and the probable life span should help determine if less stringent glycemic goals should be set. Thinner, older patients may primarily be treated with shorter-acting insulin secretagogues, low-dose sulfonylureas (preferably not long-acting ones), DPP-4 inhibitors, or α-glucosidase inhibitors. The risk for lactic acidosis, which increases with older age and the age-related decline in renal function, makes metformin therapy more problematic. In a patient whom weight gain or loss may not be unwelcome, thiazolidinediones or exenatide, respectively, may be considered, but falls risk and fracture risk must be considered with TZDs. DPP-4 inhibitors or α-glucosidase inhibitors may be advantageous due to low risk of hypoglycemia. Simple insulin regimens such as an injection of basal insulin daily may be appropriate for glycemic control in elderly patients with newly diagnosed DM.

**Gestational DM and Pregnancy with Preexisting Diabets**

Gestational DM is diagnosed as previously described. Dietary therapy to minimize wide fluctuations in blood glucose is of paramount importance.6,12 Intensive educational efforts are usually necessary. Pregnant women without DM maintain plasma glucose concentrations between 50 and 130 mg/dL. Frequent SMBG is needed to tell whether dietary interventions are successful. If

<td>Titrating: Add 1 unit/50 mg/mL &gt; 2-hr pp goal every 2 days</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Cases 2 and 3**

As above, but add and titrate analog before each meal where the postprandial glucose is above goal. Also, see part D, below for more information on how to optimize the use of analog insulin. Re-evaluate each week to be certain that about half of the total daily dose is basal and half is bolus insulin.

**B. Conversion from once-daily premix to intensive/physiologic insulin replacement:**

Oral therapy failure: once-daily 70/30 premixed insulin was added and titrated to 30 units per day. The fasting glucose is at goal, but daytime control is poor. How do you convert to physiologic insulin therapy?

a. **Basal insulin dose:** The first step in the conversion is based on the total dose of intermediate-acting insulin. In this case, the person is taking 21 units of NPH or aspart-protamine insulin (70% x 30 units = 21 units). So, give 21 units basal glargine (use "unit-for-unit" conversion for once-daily intermediate regimens.) Remember, do not stop oral agents (+ sulfonylurea) at this time.

b. **Bolus insulin dose:** There are several ways to start the analog.

i. See Case 1, page 2 (Arbitrary start or Carb-counting)

ii. Begin with the previous dose of fast-acting insulin, divide it before meals and titrate every 2 days. In this case, the person was using 30 units of 70/30 or about 9 units of fast-acting insulin (30% x 30 units = 9 units). So give 3 units of analog before each meal and titrate every 2 days as per Case 1.

**FIGURE 83-11. (continued)**

Fasting plasma glucose is >105 mg/dL, or 1-hour postprandial plasma glucose levels are >155 mg/dL, or if 2-hour postprandial plasma glucose levels are >130 mg/dL, insulin therapy is usually begun, but more aggressive use of medication is sometimes used by some clinicians. Goals during therapy are a preprandial goal of ≤95 mg/dL, and either a 1-hour postprandial plasma glucose levels ≤140 mg/dL, or 2-hour postprandial plasma glucose levels ≤120 mg/dL, and avoidance of ketones as much as possible. In patients who have preexisting type 1 or type 2 diabetes and become pregnant, premeal, bedtime, and overnight glucose should be 60 to 99mg/dL, with a peak postprandial of 100 to 129mg/dL. HbA1c during pregnancy should be less than 6%. Titration of insulin and switching to more complicated regimens is guided by SMBG results. Use of basal insulins other than NPH is still debated, but with the ease of use of detemir or glargine insulin, their use in gestational DM will likely increase. In addition, pump therapy for the duration of the pregnancy is often instituted, as it can obtain excellent glycemic control and is quickly adjustable. Despite the long-standing labeling of sulfonylureas as contraindicated in pregnancy, one randomized, open-label, controlled trial evaluated the efficacy of glyburide as compared to insulin initiated after 11 weeks’ gestation. Adequate control of blood glucose was achieved as compared to traditional insulin therapy, with less hypoglycemia in the glyburide group. No evidence of any difference in complications, specifically cord-serum insulin concentrations, incidence of macrosomia (birth weight ≥4,000 g), cesarean delivery, or neonatal hypoglycemia between regimens were noted. Glyburide was not detected in the cord serum of any infant. As the study limited enrollment beyond 11 weeks’ gestation, no conclusions regarding teratogenicity can be made from this study. The ADA cites this study in a position paper and mentions its utility, but also warns that it is not a labeled use of the drug and suggests further studies are needed to establish its safety. In addition, metformin has been studied in the treatment of GDM. Metformin crosses the placenta, but did not increase any complications associated with GDM when compared with insulin therapy, and patients
C. Conversion from twice-daily premix to intensive/physiologic insulin replacement:
Oral therapy failure in an 80 kg person: 70/30 premixed insulin was started and advanced to 60 units per day: 40 units before breakfast and 20 units before dinner. The fasting glucose was at goal, but wide glycemic excursions occurred at other times during the day and night. How do you convert this person to physiologic insulin therapy? There are several approaches. Use whichever method you want.

a. Start over and begin insulin at 0.5 units/kg. Give half as basal insulin and half as analog, divided before meals. In this case, the starting dose would be 40 units per day. Start giving 20 units glargine each morning and about 7 units analog before each meal. Titrate the basal and bolus insulins every 2 days to fasting and 2-hr postprandial goals.

b. Conversion based on current insulin usage:
   Basal dose: The first step in the conversion is based on the 80% of the total dose of intermediate-acting insulin. In this case, the person is taking 42 units of NPH or aspart-protamine insulin (70% x 60 units = 42 units). When a person is taking multiple doses of intermediate-acting insulin, we give only 80% as glargine. So, give 34 units basal glargine (80% x 42 = 34). Remember, do not stop oral agents (+ sulfonylurea) at this time.
   Bolus insulin dose: There are several ways to start the analog.
      i. See Case 1, page 3 (Arbitrary start or Carb-counting)
      ii. Begin with the previous dose of fast-acting insulin, divide it before meals and titrate every 2 days. In this case, the person was using 60 units of 70/30 or 18 units of fast-acting insulin (30% x 60 units = 18 units). So, give 6 units of analog before each meal and titrate every 2 days as per Case 1.

c. The “80%-80%” rule: Similar to the above method, but yields an ideal ratio of basal:bolus insulin in one step. The dose of basal glargine will be 80% of the total intermediate insulin, and the analog will be 80% of the glargine dose, divided before meals.
   Basal dose: = 80% of total intermediate insulin
   = 80% x 42 units (70% x 60 = 42)
   = 34 units glargine
   Analog dose: = 80% of the glargine dose, divided TID
   = 80% x 34 units = 27 units
   = 27 units, divided tid = 9 units
   = 9 units aspart, glulisine or lispro before meals

Note: Total dose of insulin is conserved and an ideal ratio between basal and bolus will always result with the “80%-80%” method.

D. Optimizing analog insulin use
Tight control of blood glucose requires that the patient participates in the management of their diabetes. This includes monitoring their blood glucose and learning to count carbohydrates or “carb count.” The following material explains how to calculate the dose of analog required to cover a meal and how to add extra analog to correct a hyperglycemic event.

a. Determining the dose of analog insulin to use before a meal
   The “Rule of 500” is used to determine how many grams of carbohydrate 1 unit of analog insulin will cover. When this number is known, then the person can easily give the correct dose of analog by simply counting the grams of carbohydrate they intend to eat at the meal.
   Specifically, 500 divided by the total daily insulin dose (500/ TDI) yields the number of grams of carbohydrate that 1 unit of analog will cover. For example, if a person has established that they require about 50 units of insulin per day, then it follows that 1 unit of analog will cover 10 grams of carbohydrate (500/50 = 10). If the person carb counts 140 grams in the dinner meal, then the dose of analog will be 14 units given 10 minutes before eating.

b. Correcting for hyperglycemia
   The “Rule of 1800” is used to determine how much insulin to use to bring a high glucose reading back to goal. Even with tight control, hyperglycemia occurs and people need to be able to correct this situation.
   Specifically, 1800 divided by the total daily insulin dose yields a value indicating how much 1 unit of analog insulin will lower the blood glucose. Thus, if a person uses 90 units of insulin per day, then 1 unit of analog will reduce the blood glucose by 20 mg/dL (1800/90 = 20). This augment dose of insulin can be used by itself to correct hyperglycemia, or added to the bolus dose if glucose is high before a meal.
preferred it overwhelmingly to insulin therapy. Further study is needed prior to recommending metformin in GDM. Patients with gestational DM should be evaluated 6 weeks after delivery to ensure that normal glucose tolerance has returned. Because these patients’ long-term risk for the development of type 2 DM is considerable, periodic assessment after that is warranted.

### SPECIAL SITUATIONS

#### Sick Days

Acute self-limited illness rarely presents a major problem for patients with type 2 DM, but can be a significant challenge for insulinopenic type 1 DM patients. While caloric intake generally declines, insulin sensitivity also decreases, meaning that it may take greater amounts of insulin to control blood glucose concentrations. Patients need to be adept at frequent SMBG, checking urine ketones, use of short-acting insulin, and understanding that sugar intake in this situation is not “bad” but may be necessary to balance the glucose levels when extra insulin is needed during illness. We encourage patients to continue their usual insulin regimen and to use supplemental rapid-acting insulin based on SMBG results, with further additional insulin given if ketonuria develops. Sugar and electrolyte solutions, such as sports drinks, can be used to maintain hydration, to provide needed electrolytes if there are significant gastrointestinal or urinary losses, and to provide sugar to keep the patient from developing hypoglycemia because of the extra insulin that is usually needed. In contrast, type 2 patients may need to switch to sugar-free drinks if blood glucose levels are continually elevated. Most patients can be taught how to sufficiently manage sick days and avoid hospitalization.

#### Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diabetic ketoacidosis and hyperosmolar hyperglycemic state are true diabetic emergencies. A comprehensive discussion of their treatment is beyond the scope of this chapter. In patients with known diabetes, diabetic ketoacidosis is usually precipitated by insulin omission in type 1 DM, and intercurrent illness, particularly infection, in both type 1 and type 2 DM. However, patients with type 1 or type 2 DM (the latter being usually non-whites or Hispanics) may present at initial presentation. It is possible that some of the patients deemed to have type 2 DM actually have type 1 idiopathic DM. Patients with diabetic ketoacidosis may be alert, stuporous, or comatose at presentation. The hallmark diagnostic laboratory values include hyperglycemia, anion gap acidosis, and large ketonemia or ketonuria. Afflicted patients have fluid deficits of several liters and sodium and potassium deficits of several hundred milliequivalents. Restoration of intravascular volume acutely with normal saline, followed by hypotonic saline to replace free water, potassium supplements, and constant infusion insulin restore the patient’s metabolic status relatively quickly. A flow sheet is often helpful in tracking the fluid and insulin therapies and laboratory parameters in these patients. Bicarbonate administration is generally not needed and may be harmful, especially in children. Treatment of the inciting medical condition is also vital. Hourly bedside monitoring of glucose and frequent monitoring (every 2–4 hours) of potassium is essential. Metabolic improvement is manifested by an increase in the serum bicarbonate or pH. Serum phosphorus usually starts high and plummets to lower-than-normal levels, though replacing phosphorus, while not unreasonable, is of questionable benefit in most patients. Fluid administration alone will reduce the glucose concentration, so a decrement in glucose values does not necessarily mean that the patient’s metabolic status is improving. Rare patients will require larger amounts of insulin than those usually given (5–10 units/h). We double the patient’s insulin dose if the serum bicarbonate has not improved after the first 4 hours of insulin therapy. Constant infusion of a fixed dose of insulin and the administration of intravenous glucose when the blood glucose level decreases to <250 mg/dL is preferable to titration of the insulin infusion based on the glucose level. The latter strategy may delay clearance of the ketosis and prolong treatment. The insulin infusion should be continued until the urine ketones clear and the anion gap closes. Long-acting insulin should be given 1 to 3 hours prior to discontinuing the insulin infusion. Intramuscular regular insulin or subcutaneous insulin lispro or aspart given every 1 to 2 hours can be utilized rather than an insulin infusion in patients without hypoperfusion. Patients may develop hyperchloremic metabolic acidosis with treatment if they have been given large volumes of normal saline in the course of their treatment. Such a situation does not require any specific treatment.

Hyperosmolar hyperglycemic state usually occurs in older patients with type 2 DM, at times undiagnosed, or in younger patients with prolonged hyperglycemia and dehydration or significant renal insufficiency. Large ketonemia is usually not seen, as residual insulin secretion suppresses the production of ketones. Infection or another medical illness is the usual precipitant. Fluid deficits are usually greater and blood glucose concentrations higher (at times >1,000 mg/dL) in these patients than in patients with diabetic ketoacidosis. Blood glucose levels should be lowered very gradually with hypotonic fluids and low-dose insulin infusions (1–2 units/h). Rapid correction of the glucose levels, a drop greater than 75 to 100 mg/dL/h, is not recommended, as it can result in cerebral edema. This is especially true for children with diabetic ketoacidosis. Mortality is high with the hyperosmolar hyperglycemic state.

#### Hospitalization for Intercurrent Medical Illness

Patients on oral agents may need transient therapy with insulin to achieve adequate glycemic control. In patients requiring insulin, patients should receive scheduled doses of insulin with additional short-acting insulin. “Sliding-scale” insulin is to be discouraged, as it is notorious for not controlling glucose and for sometimes resulting in therapeutic misadventures, with wide swings in the blood glucose as the patient “bounces” from hypoglycemia to hyperglycemia. In-hospital mortality is increased in many hyperglycemic conditions. At least one study documented a reduction in mortality in type 2 diabetes patients with acute MIs who receive constant intravenous insulin during the acute phase of the event to maintain near-normal glucose concentrations. Similar mortality results have been documented in some intensive care unit settings using intravenous insulin and tight glucose control. The American Diabetes Association and American Association of Clinical Endocrinologists released a joint consensus statement on inpatient glycemic control stating that glucose control measures should be implemented if the blood glucose is ≥180 mg/dL, and maintained between 140 and 180 mg/dL. The Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation trial, and several other negative trials, have resulted in this loosening of inpatient glycemic goals. Critically ill patients had a higher 90-day mortality when a goal of 81 to 108 mg/dL was targeted than when a blood glucose of ≤180 mg/dL (achieved 144 mg/dL) was targeted. Many protocols for IV insulin infusion are currently available, and implementation for an inpatient setting should use a well-established protocol. It is prudent to stop metformin in all patients who arrive in acute care settings until full elucidation of the reason for presentation can be ascertained, as contraindications to metformin are prevalent in hospitalized patients.
Perioperative Management
Surgical patients may experience worsening of glycemia for reasons similar to those listed above for intercurrent medical illness.\textsuperscript{109} Patients on oral agents may need transient therapy with insulin to control blood glucose. In patients requiring insulin, scheduled doses of insulin or continuous insulin infusions are preferred. For patients who can eat soon after surgery, the time-honored approach of giving one-half of the usual morning NPH insulin dose with dextrose 5% in water intravenously is acceptable, with resumption of scheduled insulin, perhaps at reduced doses, within the first day. For patients requiring more prolonged periods without oral nutrition and for major surgery, such as coronary artery bypass grafting and major abdominal surgery, constant infusion intravenous insulin is preferred. Use of intravenous insulin infusion has been shown to reduce deep sternal wound infections in patients after coronary artery bypass grafting, though there is no need to start the infusion during or before the procedure. Metformin should be discontinued temporarily after any major surgery until it is clear that the patient is hemodynamically stable and normal renal function is documented.

Reproductive-Age Women and Preconception Care for Women
An increasing prevalence of DM has been noted in reproductive-age women.\textsuperscript{101,102} Prepregnancy planning is absolutely mandatory, as between 6% and 10% of pregnancies occur in women who report diabetes in their family history.\textsuperscript{102} Preconception care for women with DM may need intensification of their regimen to achieve therapeutic goals. Normal pregnancy is associated with a decrease in the blood glucose concentrations should be the target of therapy is not hotly debated. Patients previously treated with insulin may need intensification of their regimen to achieve therapeutic goals.

SPECIAL TOPICS

Prevention of Diabetes Mellitus
- Efforts to prevent type 1 DM with immunosuppressives, niacinamide, injected insulin, or oral insulin therapy have been unsuccessful. The Diabetes Prevention Program\textsuperscript{106} confirmed that modest weight loss in association with exercise can have a dramatic impact on insulin sensitivity and the conversion from impaired glucose tolerance to type 2 diabetes. In this study approximately 2,000 individuals with impaired glucose tolerance were randomized to lifestyle changes (diet, exercise, and weight loss) versus usual care. The study, which was originally planned to be ongoing for 5 years, was stopped after 2.8 years because the results were so conclusive. The usual care group developed diabetes at the rate of 11% each year. The lifestyle arm developed diabetes at a rate of 5% per year, a 58% reduction in the risk of developing diabetes. Surprisingly, a modest amount of diet and exercise yielded impressive results. The exercise program in the lifestyle group was walking 30 minutes 5 days each week. The mean weight loss over the 2.8-year study period was only 8 pounds. Similar results were seen in the Finnish Diabetes Study.\textsuperscript{107} In the Diabetes Prevention Program\textsuperscript{106} discussed above, approximately 1,000 of the study patients were randomized to metformin therapy. Metformin therapy reduced the risk of developing type 2 DM by 31% compared to usual care and resulted in a 4-pound weight loss. Interestingly, young and overweight individuals on metformin had a greater reduction in the incidence of developing diabetes than normal weight and older study patients.\textsuperscript{106}

Metformin and acarbose appear to mostly be treating early diabetes, because when the drugs were stopped, diabetes rates were close to the conversion rates for placebo. In contrast, the TRIPOD study\textsuperscript{108} evaluated the ability of troglitazone to prevent the development of diabetes in women with a history of gestational diabetes. The rate of development of diabetes in the placebo arm of the study was approximately 12% per year, compared with about 5% in the treatment group. Total preservation of β-cell function was demonstrated over a 5-year period in women who had normal β-cell function at baseline and who initially responded to the drug. The preservation of β-cell function was observed for at least 8 months after the drug had been discontinued. The DREAM trial evaluated rosiglitazone and/or ramipril treatment for the delay or prevention of type 2 DM in impaired glucose tolerant subjects. Rosiglitazone 8 mg daily, over approximately 3 years, reduced the incidence of type 2 diabetes by 60%. In addition, a 37% nonsignificant increase in cardiovascular events was reported. Ramipril 15 mg daily did not significantly prevent the conversion to diabetes. It is possible that longer exposure could have made a difference, but the study was stopped prematurely. In contrast, valsartan, and angiotensin-receptor blocker (ARB), administered for 5 years was recently reported to reduce the risk of progression from impaired glucose tolerance to type 2 DM by 14%. The ACT Now trial used pioglitazone 45 mg daily in an IGT population and found an 81% reduction in the risk of development of diabetes over 3 years. It should be noted that no pharmacologic agents are currently FDA approved or recommended for prevention of type 2 diabetes, although the ADA recommends metformin in conjunction with lifestyle changes if the patient is younger, obese, has a family history of diabetes, dyslipidemia, hypertension, or a HbA\textsubscript{1c} >6%. The next step is discussions with the FDA to decide how and if medications to prevent diabetes can be approved for this indication.

CLINICAL CONTROVERSY
Diabetes mellitus is associated with a substantially higher risk of morbidity and mortality. Pharmacologic prevention or delay of type 2 DM has been widely discussed since the release of the Diabetes Prevention Program results. Though lifestyle changes were effective, with a 58% lower relative risk of progression to diabetes, metformin 850 mg twice a day reduced the risk by 31%, and was essentially as effective as diet and exercise in
young/obese subjects. Pioglitazone, rosiglitazone, acarbose, and even orlistat all have, to one extent or another, been able to delay the onset of type 2 DM. Despite these data, there are no FDA-approved drugs for the delay or prevention of diabetes. The ADA-recommended medications, in conjunction with lifestyle, for the delay or prevention of type 2 DM include metformin. It should be remembered that medications require monitoring and can have serious side effects. Many feel they are simply treating diabetes early, as there is considerable beta-cell dysfunction documented in early impaired glucose tolerant subjects. Other than troglitazone, which is not on the market, no medication has clearly shown beta-cell preservation. It is logical to try to use medications if they alter the decline of beta-cell function, but this is currently off-label use and any attempt to use medication in these situations should be clearly and frankly discussed with the patient.

Patient Education

It is not satisfactory to give patients with DM brief instructions with a few pamphlets and expect them to manage their disease adequately. Thinking that diabetes education is limited to one or two encounters is misguided; education is a lifetime exercise. Successful treatment of DM involves lifestyle changes for the patient (e.g., medical nutrition therapy, physical activity, self-monitoring of blood glucose and possibly of urine for ketones, recognition of hyper- and hypoglycemia, and taking prescribed medications). The American Association of Diabetes Educators (AADE) has developed the AADE7 self-care behaviors of healthy eating, being active, monitoring, taking medication, problem solving, reducing risk, and healthy coping, which is a good starting framework for patient discussions. The patient must be involved in the decision-making process and must learn as much about the disease and associated complications as possible. Emphasis should be placed on the evidence that indicates that complications can be prevented or minimized with glycemic control and management of risk factors for cardiovascular disease. Recognition of the need for proper patient education to empower them into self-care has generated programs for certification in diabetes education for pharmacists. Certified diabetes educators (CDEs) must document their patient education hours and sit for a certification examination that assesses the knowledge, tasks, and skills of an educator in order to become certified. An increasing number of nurses, pharmacists, dietitians, and physicians are becoming CDEs to document to the public that they meet a minimum standard for diabetes education, and to fulfill quality initiatives in meeting guidelines for education recognition. Being a CDE does not guarantee reimbursement of services, and CDEs who are not dietitians will often need to become part of a recognized program to obtain reimbursement. Currently the AADE and ADA have accreditation programs.

TREATMENT OF CONCOMITANT CONDITIONS AND COMPLICATIONS

Retinopathy

Patients with established retinopathy should see an ophthalmologist or optometrist trained in diabetic eye disease. A dilated eye exam is required to fully evaluate diabetic eye disease. Early background retinopathy may reverse with improved glycemic control. More advanced retinopathy will not regress with improved glycemia, and may actually worsen with short-term improvements in glycemia. Studies are under way to determine whether medical therapy independent of glucose control will prevent the development of advanced retinopathy. Laser photocoagulation has markedly improved sight preservation in diabetic patients.

Neuropathy

Peripheral neuropathy is the most common complication seen in type 2 DM patients in outpatient clinics. Paaresthesias, numbness, or pain may be the predominant symptom. The feet are involved far more often than the hands. Improved glycemic control may alleviate some of the symptoms. If neuropathy is painful, symptomatic therapy is empiric, including low-dose tricyclic antidepressants, anticonvulsants (gabapentin, pregabalin, carbamazepine, and maybe phenytoin), duloxetine, venlafaxine, topical capsaicin, and various pain medications, including tramadol and nonsteroidal antiinflammatory drugs. Recently, another anticonvulsant, topiramate, has shown promise in the reduction of symptoms, with the positive side effect of weight loss in type 2 diabetes patients, though tolerability is problematic. The numb variant of peripheral neuropathy is not treated with medication. Clinical manifestations of diabetic autonomic neuropathy include resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, sudomotor dysfunction (anhidrosis, heat intolerance, gustatory sweating, and/or dry skin), impaired neurovascular function, and hypoglycemic autonomic failure. Gastroparesis can be a severe and debilitating complication of DM. Improved glycemic control, discontinuation of medications that slow gastric motility, and the use of metoclopramide (preferably for only a few weeks at a time) or erythromycin may be helpful. Gastric pacemakers as therapeutic hardware are rarely used, though available, and cisapride, removed from the market several years ago, is still available for compassionate use. Orthostatic hypotension may require pharmacologic management with mineralocorticoids or adrenergic agonist agents. In severe cases, supine hypertension is extreme, mandating that the patient sleep in a sitting or semirecumbent position. Patients with cardiac autonomic neuropathy are at a higher risk for silent MI and mortality. The hallmark of diabetic diarrhea is its nocturnal occurrence. Diabetic diarrhea frequently responds to a 10- to 14-day course of an antibiotic such as doxycycline or metronidazole. In more unresponsive cases, octreotide may be useful. Erectile dysfunction is common in diabetes, and initial treatment should include a trial of one of the oral medications currently available to treat erectile dysfunction. People with diabetes often require the highest doses of these medications to have an adequate response. Sudomotor dysfunction, as earlier defined, results in loss of sweating and resultant dry, cracked skin. Use of hydrating creams andointments is needed.

Microalbuminuria and Nephropathy

Diabetes mellitus, particularly type 2 DM, is the biggest contributor statistically to the development of endstage renal disease in the United States. The American Diabetes Association recommends a screening urinary analysis for albumin at diagnosis in persons with type 2 DM. Precise onset of type 2 DM can rarely be ascertained, and patients will often present at diagnosis with microvascular complications. In type 1 DM, microalbuminuria rarely occurs with short duration of disease or before puberty. Screening individuals with type 1 DM should begin with puberty and after 5 years’ disease duration. There are three methods for assessing microalbuminuria: (1) measurement of the urine albumin:creatinine ratio in a random spot collection (preferably the first morning void); (2) 24-hour timed collection; and (3) timed (e.g., 4- or 10-hour overnight) collection. Microalbuminuria on a spot urine specimen is defined as a
ratio of 30 to 300 mg/g albumin:creatinine. On timed collections, microalbuminuria is defined as 30 to 300 mg/24 hours or an albumin excretion rate of 20 to 200 mcg/min. Because of day-to-day variability, microalbuminuria should be confirmed on at least two of three samples over 3 to 6 months. Additionally, when assessing urine protein or albumin, conditions that may cause transient elevations in urinary albumin excretion should be excluded. These conditions include intense exercise, recent urinary tract infections, hypertension, short-term hyperglycemia, heart failure, and acute febrile illness.

In type 2 DM, the presence of microalbuminuria is a strong risk factor for macrovascular disease and is frequently present at the time of diagnosis. Microalbuminuria is a weaker predictor for future kidney disease in type 2 versus type 1 DM.

Glucose and blood pressure control are most important for the prevention of nephropathy, and blood pressure control is the most important for retarding the progression of established nephropathy. ACE inhibitors and ARBs, considered first-line recommended treatment modalities, have shown efficacy in preventing the clinical progression of renal disease in patients with type 2 DM. Diuretics are necessary due to the volume-expanded state of the patient and are recommended second-line therapy. The American Diabetes Association and the National Kidney Foundation blood pressure goal of <130/80 mm Hg can be difficult to achieve. Three or more antihypertensives are often needed to treat to goal blood pressures.

Peripheral Vascular Disease and Foot Ulcers
Claudication and nonhealing foot ulcers are common in type 2 DM patients. Smoking cessation, correction of lipid abnormalities, and antiplatelet therapy are important strategies in treating claudicants. Cilostazol may be useful for reducing intermittent claudication symptoms in select patients. Revascularization is successful in selected patients, though small vessel disease that cannot be bypassed is common in diabetes. Local debridement and appropriate footwear and foot care are vitally important in the early treatment of foot lesions. In more advanced lesions, topical treatments may be of benefit. Diabetic foot care is an excellent example of the adage, “an ounce of prevention is worth a pound of cure.”

Coronary Heart Disease
The risk for coronary heart disease (CHD) is 2 to 4 times greater in diabetic patients than in nondiabetic individuals. CHD is the major source of mortality in patients with DM. Recent studies suggest that multiple risk factor intervention (lipids, hypertension, smoking cessation, and antiplatelet therapy) will reduce the burden of excess macrovascular events. The ADA recommends aspirin therapy in all secondary prevention situations, and if allergic to aspirin, consider clopidogrel. Recent evidence in primary prevention studies of antiplatelet therapy in type 2 DM have not shown benefit. The ADA currently recommends that if the 10-year risk of CVD is at least 10%, or the patient is at your judgment high risk, or in women at least 50 years old or men at least 60 years old, primary prevention antiplatelet therapy can be considered. Epidemiologic data suggest that CHD prevention guidelines for type 2 DM apply equally to patients with type 1 DM. β-Blocker therapy supplies an even greater protection from recurrent CHD events in diabetic patients than in nondiabetic subjects. Masking of hypoglycemic symptoms is a greater problem in type 1 DM patients than in patients with type 2 DM.

Lipids
The Collaborative Atorvastatin Diabetes Study (CARDs) randomized diabetes subjects with no documented cardiovascular disease to atorvastatin 10 mg daily (n = 1,428) or placebo (n = 1,410). The trial was stopped 2 years early (mean duration of follow-up was 3.9 years) after meeting the primary efficacy endpoint of major cardiovascular events, which were reduced by 37% (P = 0.001). All-cause death was reduced 27% (P = 0.059), and potentially could have had its significance influenced by the early stoppage of the trial. The Heart Protection Study randomized 5,963 patients age >40 years with diabetes and total cholesterol >135 mg/dL. A significant 22% reduction (95% CI, 13–30) in the event rate for major cardiovascular events was seen with simvastatin 40 mg/day. This was evident even at lower LDL levels (<116 mg/dL), and suggests that ~30% to 40% reduction in LDL levels regardless of starting LDL levels may be appropriate. The proper use of fibrates in diabetes continues to be controversial. The diabetic subgroup in the Veterans Administration HDL Intervention Trial (VA-HIT) of CHD patients with low LDL-C and low LDL-C showed approximately 22% reduction in CHD events in diabetic patients with known CHD when LDL-C was increased by approximately 6% by gemfibrozil. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) was conducted in 9,795 subjects (22% with previously documented CVD) with type 2 DM given fenofibrate 200 mg daily or placebo. A relative reduction of 11% (P = 0.16) was seen in any coronary event in conjunction with a slight increase in the risk of all-cause mortality (0.7%; P = 0.18). Reasons for this have been speculated on, including the increased use of statins in the placebo group, but continue to be controversial. On subset analysis, only subjects without CVD had a significant reduction in CVD events. The lipid arm of the ACCORD guidelines report on 5,518 subjects randomized to fenofibrate or placebo given with low-dose simvastatin (~20 mg/day). Fenofibrate addition did not significantly lower cardiovascular events (0.92; 95% CI, 0.79–1.08). On subgroup analysis, women had a 30% higher risk of adverse cardiovascular outcomes, but this was not seen in the FIELD trial. In addition, the only subjects who had a lowering of CVD risk were subjects with high triglycerides combined with low LDL-C.

The National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP) guidelines classify the presence of DM as a CHD risk equivalent, and therefore recommend that LDL-C be lowered to <100 mg/dL. An optional LDL goal in high-risk DM patients, such as those who already have CHD, has been updated to <70 mg/dL. Unlike previous guidelines, more consideration is now given to HDL-C and triglycerides. The primary target is the treatment of LDL-C. After the LDL-C goal is reached (usually with a statin), via NCEP-ATP, triglycerides are possibly considered for pharmacologic management, assuming unresponsiveness to glycemic control efforts, weight management, and exercise. In such situations, a non–HDL-C goal is established (a surrogate for all apolipoprotein B–containing particles). The non–HDL-C goal for patients with DM is <130 mg/dL. Niacin or a fibrate can be added to reach that goal if triglycerides are 201 to 499 mg/dL. NCEP-ATP states that niacin or a fibrate can also be added if the LDL-C goal is reached, but if the patient has low HDL-C (<40 mg/dL), fibrates have very little, if any positive effect on HDL-C. Patients with marked hypertriglyceridemia (≥500 mg/dL) are at risk for pancreatitis. Efforts to reduce triglycerides with glycemic control, elimination of other secondary causes (including medications), and drug therapy (fibrate and/or niacin) are effective treatment strategies. The ADA also recommends similar LDL goals, but places raising HDL as the second priority (Table 83–16). The definitive role of pharmacologic therapy of HDL-C and/or hypertriglyceridemia in type 2 DM patients (beyond that seen with statin therapy) has yet to be proven in clinical trials, but is leaning heavily toward HDL-C being a very important second priority for the prevention of CVD.
Hypertension

The role of hypertension in increasing microvascular and macrovascular risk in patients with DM has been confirmed in the UKPDS90 and Hypertension Optimization Treatment124 trials. The American Diabetes Association recommends aggressive goals for blood pressure (<130/80 mm Hg) in patients with DM. A The ACCORD blood pressure arm studied type 2 DM patients, with a goal of achieving a systolic blood pressure of either <120 mm Hg (achieved 119 mm Hg) or <140 mm Hg (133 mm Hg achieved).125 The lower pressure group did not have lower CVD or renal outcomes, but did lower the risk of stroke. ACE inhibitors and ARBs are generally recommended for initial therapy, as they have shown to be cardioprotective, and likely have special renal protection. Many patients require multiple agents, on average three agents, to obtain goals, so diuretics, calcium channel blockers, and β-blockers frequently are useful as second and third agents. African Americans need special consideration. African Americans receive renoprotection from ACE inhibitors or ARBs, but as a population may lower blood pressure slightly less with these agents. It is recommended that combination therapy with a diuretic or calcium channel blocker be considered as first-line therapy. After initial therapy, which agent to add next is still controversial. Blood pressure goals are generally more difficult to achieve than glycemic goals or lipid goals in most diabetic patients.

### CLINICAL CONTROVERSY

The use of fibric acid derivatives and ezetimibe continues to be controversial in the treatment of dyslipidemia in diabetes patients. The FIELD trial using fenofibrate did not result in similar CVD reductions that have been documented in diabetes statin trials. The ACCORD lipid arm in type 2 DM patients added fenofibrate to low-dose simvastatin and did not lower the risk of CVD. The VA-HIT trial using gemfibrozil, though a subset, has shown a reduction in CVD outcomes. Fibric acid derivatives should be considered at least third-line therapy, unless triglycerides are high enough that LDL-C is not reported. It is reasonable to consider use of gemfibrozil as the first fibric acid derivative in diabetes subjects based on the FIELD and ACCORD data. If the drug–drug interaction of a statin with a fibric acid derivative is of paramount importance to the clinician, fenofibrate can be considered. Ezetimibe, and whether it can reduce CVD, continues to be controversial. Colesevelam, which does not have CVD outcomes in diabetes patients, may be a better choice as it will decrease LDL-C in conjunction with a statin, and has the added benefit of a modest reduction in HbA1c. Neither should be considered until statin therapy is optimized.

Transplantation

Whole pancreas and islet cell transplantation are still relatively experimental procedures in patients with type 1 DM; those with endstage renal disease also receive kidney transplantation.128

### PHARMACOECONOMIC CONSIDERATIONS

As described in the introduction, the direct and indirect costs of DM are substantial. Much of the indirect costs are related to loss of productivity due to the significant morbidity (hospitalizations, loss of vision, lower extremity amputations, kidney failure, and cardiovascular events) associated with the disease. For a disease that affects about 8% of the population, it is responsible for 11% to 12% of health expenditures (in 2007, direct $116 billion, indirect $58 billion). With evidence from the DCCT and UKPDS to support intensive blood glucose control to reduce the risk of complications, the question of cost-effectiveness comes into play. An economic model based on the DCCT approximates that 120,000 persons in the United States would meet criteria for intensive intervention. The cost of implementing intensive therapy over the lifetime of the population is estimated at $4 billion. The benefits of this strategy are net gains of 920,000 years of sight, 691,000 years free from endstage renal disease, and 678,000 years free from lower extremity amputations. The incremental cost per year of life gained is $28,661.127 This is well within the limits of a cost-effective strategy and compares favorably to treatment of high blood pressure or hypercholesterolemia.
for the prevalence of CVD in type 2 DM, an estimate of $16,002 incremental cost per quality-adjusted life-year gained was obtained. The limitation of this analysis is that while the UKPDS did demonstrate an improvement in diabetes-related outcomes, the overall efficacy on microvascular disease complications was not mirrored by the DCCT.

Two economic analyses were performed on data generated from the UKPDS, one assessing cost-effectiveness of an intensive blood glucose control policy in type 2 DM, and the other assessing improved blood pressure control in hypertensive patients with type 2 DM. In the first analysis, outcome was measured as the incremental cost per event-free year gained within the trial. Based on trial outcomes and assumptions, the incremental cost in the intensive treatment group per event-free year gained is $1,366. While intensive treatment costs were higher, the cost per event-free year gained appears cost-effective. The second analysis showed the incremental cost per extra year free from microvascular and macrovascular endpoints from intensive blood pressure control in a standard clinical practice model to be $1,498. The incremental cost per life-year gained was estimated at $619, again, demonstrating the cost-effectiveness of intensive intervention.¹³⁰,¹³¹

### EVALUATION OF THERAPEUTIC OUTCOMES

### MONITORING OF THE PHARMACEUTICAL CARE PLAN

A comprehensive pharmaceutical care plan for the patient with DM will integrate considerations of goals to optimize blood glucose control and protocols to screen for, prevent, or manage microvascular and macrovascular complications. In terms of standards of care for persons with DM, one can review the document published by the American Diabetes Association that outlines initial and ongoing assessments for patients with DM.¹ The major performance measure by the National Committee for Quality Assurance (NCQA), such as Health Plan Employer Data and Information Set (HEDIS), should assess the ability to meet current standards of care and recognize the minimal treatment goals for glycemia, lipids, and hypertension, and provide targets for monitoring and adjusting pharmacotherapy as discussed in various sections above. Publicly reported quality measures continue to move closer to current guidelines, but lack the ability to differentiate reasons why a patient is not controlled. Glycemic control (tested minimally yearly; HbA₁c <8% is good control and HbA₁c >9% is poor control), lipid (percentage of patients with LDL <100 mg/dL), and hypertension (percentage of patients with blood pressure <130/80 mm Hg, but also with blood pressure <140/90) are NCQA-based measures. Glycemic control is paramount in managing type 1 or type 2 DM, but as readily identified from the above discussion, it requires frequent assessment and adjustment in diet, exercise, and pharmacologic therapies. The ADA also has clinical practice recommendations that are widely cited and followed.⁵ Minimally, HbA₁c should be measured twice a year in patients meeting treatment goals on a stable therapeutic regimen. Quarterly assessments are recommended for those whose therapy has changed or who are not meeting glycemic goals. Fasting lipid profiles should be obtained as part of an initial assessment and thereafter at each follow-up visit if not at goal, annually if stable and at goal, or every 2 years if the lipid profile suggests low risk. Documenting regular frequency of foot exams (each visit), urine albumin assessment (annually), dilated ophthalmologic exams (yearly or more frequently with identified abnormalities), and office visits for follow-up are also important. Assessment for pneumococcal vaccine administration (and one time revaccination recommended in individuals at least 65 years old), annual administration of influenza vaccine, and routine assessment for and management of other cardiovascular risks (e.g., smoking and antiplatelet therapy) are components of preventive medicine strategies. The multiplicity of assessments for each patient visit are likely to be better facilitated utilizing an integrative computer program and electronic medical record, standardized progress note forms, or flow sheets, which assist the clinician in identifying whether the patient has met standards of care in the frequency of monitoring and achievement of defined targets of therapy.

The molecular biology of the thyroid hormones and their receptors has provided an in-depth understanding of the various mutations that give rise to hyper- and hypothyroidism. Thyrotoxicosis is most commonly caused by Graves’s disease, which is an autoimmune disorder in which thyroid-stimulating antibody (TSAb) directed against the thyrotropin receptor elicits the same biologic response as thyroid-stimulating hormone (TSH). Hyperthyroidism may be treated with antithyroid drugs such as propylthiouracil (PTU) or methimazole (MMI), radioactive iodine (RAI: 131I), or surgical removal of the thyroid gland; selection of the initial treatment approach is based on patient characteristics such as age, concurrent physiology (e.g., pregnancy), comorbidities (e.g., chronic obstructive lung disease), and convenience. PTU and MMI reduce the synthesis of thyroid hormones and are similar in efficacy and adverse effects, but their dosing ranges differ by 10-fold. Response to PTU and MMI is seen in 4 to 6 weeks with a maximal response in 4 to 6 months; treatment usually continues for 1 to 2 years, and therapy is monitored by clinical signs and symptoms and by measuring the serum concentrations of TSH and free thyroxine (T4). Many patients choose to have ablative therapy with 131I rather than undergo repeated courses of PTU or MMI; most patients receiving RAI eventually become hypothyroid and require thyroid hormone supplementation. Adjunctive therapy with β-blockers controls the adrenergic symptoms of thyrotoxicosis but does not correct the underlying disorder; iodine may also be used adjunctively in preparation for surgery and acutely for thyroid storm. Hypothyroidism is most often due to an autoimmune disorder known as Hashimoto’s thyroiditis, and the drug of choice for replacement therapy is levothyroxine.

Monitoring of levothyroxine replacement therapy is achieved by observing clinical signs and symptoms and by measuring the TSH (elevated for underreplacement, suppressed for overreplacement).

Thyroid hormones affect the function of virtually every organ system. In the child, thyroid hormone is critical for normal growth and development. In the adult, the major role of thyroid hormone is to maintain metabolic stability. Substantial reservoirs of thyroid hormone in the thyroid gland and blood provide constant thyroid hormone availability. In addition, the hypothalamic–pituitary–thyroid axis is exquisitely sensitive to small changes in circulating thyroid hormone concentrations, and alterations in thyroid hormone secretion maintain peripheral free thyroid hormone levels within a narrow range. Patients seek medical attention for evaluation of symptoms due to abnormal thyroid hormone levels or because of diffuse or nodular thyroid enlargement.

**THYROID HORMONE PHYSIOLOGY**

### THYROID HORMONE SYNTHESIS

The thyroid hormones thyroxine (T4) and triiodothyronine (T3) are formed on thyroglobulin, a large glycoprotein synthesized within the thyroid cell (Fig. 84–1). Because of the unique tertiary structure of this glycoprotein, iodinated tyrosine residues present in thyroglobulin are able to bind together to form active thyroid hormones.1 Iodide is actively transported through the basolateral membrane via a Na+/I− symporter from the extracellular space into the thyroid follicular cell against an electrochemical gradient, driven by the coupled transport of sodium.2 Structurally related anions such as SCN− (thiocyanate), ClO4− (perchlorate), and TcO4− (pertechnetate) are competitive inhibitors of iodine transport.3 In addition,
Thyroid Hormone Synthesis and Secretion

\]

bromine, fluorine, and under certain circumstances lithium, block iodide transport into the thyroid (Table 84–1). Inorganic iodide that enters the thyroid follicular cell is ushered through the cell to the apical membrane, where it is transported into the follicular lumen by at least two efflux channels. 4,5 Located on the luminal side of the apical membrane, thyroid peroxidase oxidizes iodide and covalently binds the organified iodide to tyrosine residues of thyroglobulin (Fig. 84–2). It is interesting that although salivary glands and the gastric mucosa are able to actively transport iodide, they are unable to effectively incorporate iodide into proteins given the lack of similar oxidizing machinery. Similarly, when tyrosine molecules are iodinated on proteins other than thyroglobulin, they lack the proper tertiary structure needed to allow the formation of active thyroid hormones.

The iodinated tyrosine residues monoiodotyrosine (MIT) and diiodotyrosine (DIT) combine to form iodothyronines (organification of the iodine). MIT and DIT combine to form triiodothyronine (T3) or two molecules of DIT combine to form thyroxine (T4).

Iodine deficiency causes an increase in the ratio of MIT to DIT in thyroglobulin and leads to a relative increase in the production of T3. Because T3 is more potent than T4, the increase in T3 production in iodine-depleted areas may be beneficial. The thionamide drugs used to treat hyperthyroidism inhibit thyroid peroxidase and thus block thyroid hormone synthesis.

Thyroglobulin is stored in the follicular lumen and must reenter the cell, where the process of proteolysis liberates thyroid hormone into the bloodstream. Thyroid follicles active in hormone synthesis are identified histologically by columnar epithelial cells lining follicular lumens, which are depleted of colloid. Inactive follicles are identified histologically by columnar epithelial cells lining follicular lumens and are replete with colloid. Both iodide and lithium block the release of preformed thyroid hormone, through poorly understood mechanisms.

T4 and T3 are transported in the bloodstream primarily by three proteins: thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin. 6 It is estimated that 99.96% of circulating T4 and 99.5% of T3 are bound to these proteins. However, only the unbound (free) thyroid hormone is able to diffuse into the cell, elicit a biologic effect, and regulate thyroid-stimulating hormone (TSH; also known as thyrotropin) secretion from the pituitary. Multiple functions have been ascribed to these transport proteins, including (1) assuring minimal urinary loss of iodide, (2) providing a mechanism for uniform tissue distribution of free hormone, and (3) transport of hormone into the central nervous system. Whereas T4 is secreted solely from the thyroid gland, less than 20% of T4 is produced in the thyroid. The majority of T4 is formed from the breakdown of T3 catalyzed by the enzyme 5′-monodeiodinase found in extrathyroidal peripheral tissues. Because the binding affinity of nuclear thyroid hormone receptors is 10 to 15 times higher for T3 than T4, the deiodinase enzymes play a pivotal role in determining overall metabolic activity. Three different monodeiodinase enzymes are present in the body. 6 Of the enzymes that catalyze 5′-monodeiodination, type I enzymes are present in peripheral tissues, whereas type II enzymes are found in the central nervous system, pituitary, and thyroid. Type III enzymes, found in the placenta, skin, and developing brain, inactivate T3 and T4 by deiodinating the inner ring at the 5 position. The principal characteristics of these enzymes are listed in Table 84–2. T4 may also be acted on by the enzyme 5′-monodeiodinase to form reverse T3, but this accounts for a small component of hormone metabolism. Polymorphisms in the deiodinase genes may prove to be of clinical significance. For example, a polymorphism in the type I deiodinase leading to increased activity seems to be associated with an increased circulating ratio of free T3 to free.
T<sub>r</sub>. Reverse T<sub>r</sub> has no known significant biologic activity. T<sub>r</sub> is removed from the body by deiodinative degradation and through the action of sulfotransferase enzyme systems converting to T<sub>3</sub> sulfate and 3,3-diiodothyronine sulfates, thus facilitating enterohepatic clearance. Thyronamines are derivatives of thyroid hormone that are present in very low concentrations in human serum. The most studied thyronamine, 3-iodothyronamine, can theoretically be made from thyroxine by decarboxylation and deiodination. Administration of pharmacologic amounts of 3-iodothyronamine to animals has profound effects on temperature regulation and cardiac function, and shifts fuel metabolism from carbohydrates to lipids. However, a possible physiological role for thyronamines has yet to be determined.<sup>10</sup>

The growth and function of the thyroid are stimulated by activation of the thyrotropin receptor by TSH. The receptor belongs to the family of G-protein–coupled receptors. The thyrotropin receptor is coupled to the α subunit of the stimulatory guanine-nucleotide–binding protein (G<sub>α</sub>), activating adenylate cyclase and increasing the accumulation of cyclic adenosine monophosphate. Through this mechanism, TSH stimulates the expression of thyroglobulin and thyroid peroxidase genes as well as increases apical iodide efflux. Somatic activating mutations in the receptor are commonly seen in autonomously functioning thyroid nodules.<sup>11</sup> Rarely, germline activating mutations of the TSH receptor have been reported in kindreds with Leclere syndrome, and thyrotoxicosis can result from germline activating mutations in G-protein signaling in McCune-Albright syndrome.<sup>11,13-15</sup>

Conversely, thyrotropin resistance would result from point mutations that prevent TSH binding, leading to abnormalities in the thyrotropin receptor–adenylate cyclase system and congenital hypothyroidism.<sup>16,17</sup> Individuals with this abnormality have high levels of T<sub>4</sub> but decreased thyroglobulin levels and a normal or small gland.

Thyroid hormone receptors regulate the transcription of target genes in the presence of physiologic concentrations of T<sub>r</sub>. Unlike most other nuclear receptors, thyroid hormone receptors also actively regulate gene expression in the absence of hormone, typically resulting in an opposite effect. Thyroid receptors translocate from the cytoplasm to the nucleus, interact in the nucleus with T<sub>3</sub> and target genes and other proteins required for basal and T<sub>3</sub>-dependent gene transcription. Thyroid receptors exist in three isoforms, TR<sub>β</sub>2, TR<sub>β</sub>1, and TR<sub>α</sub>1, with variation in the expression of each in differing tissues. There is interest in developing thyroid hormone analogues that selectively activate specific TR isoforms. Such agents could theoretically have targeted desirable effects such as stimulating energy expenditure without having adverse effects on other tissues.<sup>19</sup>

The production of thyroid hormone is regulated in two main ways. First, thyroid hormone is regulated by TSH secreted by the anterior pituitary. The secretion of TSH is itself under negative feedback control by the circulating level of free thyroid hormone and the positive influence of hypothalamic thyrotropin-releasing hormone (TRH). Second, extrathyroidal deiodination of T<sub>4</sub> to T<sub>3</sub> is regulated by a variety of factors including nutrition, nonthyroidal hormones, ambient temperatures, drugs, and illness.

### THYROTOXICOSIS

Thyrotoxicosis results when tissues are exposed to excessive levels of T<sub>4</sub>, T<sub>r</sub>, or both.<sup>20</sup> In the National Health and Nutrition Examination Survey III, 0.7% of those surveyed who were not taking thyroid medications and had no history of thyroid disease had subclinical hyperthyroidism (TSH <0.1 milli-international units/L; and T<sub>4</sub> normal), and 0.5% had “clinically significant” hyperthyroidism (TSH <0.1 milli-international units/L; and T<sub>4</sub> >13.2 mcg/dL).<sup>21</sup> The prevalence of suppressed TSH peaked for people aged 20 to 39, declined in those 40 to 79, and increased again in those 80 or older. Abnormal TSH levels were more common among women than among men.

### CLINICAL PRESENTATION OF THYROTOXICOSIS

#### General
- Signs and symptoms of hyperthyroidism affect multiple organ systems. Patients may have symptoms for an extended time period before the diagnosis of hyperthyroidism is made.

#### Symptoms
- The typical clinical manifestations of thyrotoxicosis include nervousness, anxiety, palpitations, emotional lability, easy fatigability, menstrual disturbances, and heat intolerance. A cardinal sign is loss of weight concurrent with an increased appetite.

#### Signs
- A variety of physical signs may be elicited including warm, smooth, moist skin, exophthalmos (in Graves’s disease only), pretibial myxedema (in Graves’s disease only), and unusually fine hair. Separation of the end of the fingernails from the nail beds (onycholysis) may be noted. Ocular signs that result from thyrotoxicosis include retraction of the eyelids and lagging of the upper lid behind the globe when the patient looks downward (lid lag). Physical signs of a hyperdynamic circulatory state are common and include tachycardia at rest, a widened pulse pressure, and a systolic ejection murmur. Gynecomastia is sometimes noted in men. Neur muscular examination often reveals a fine tremor of the protruded tongue and outstretched hands. Deep tendon reflexes are generally hyperactive. Thyromegaly is usually present.

#### Diagnosis
- Low TSH serum concentration. Elevated free and total T<sub>3</sub> and T<sub>4</sub> serum concentrations, particularly in more severe disease.
For the elderly patient and for the patient with very severe disease, anorexia may be present as well. Elderly patients are also more likely to develop atrial fibrillation with thyrotoxicosis than younger patients. The frequency of bowel movements may increase, but frank diarrhea is unusual. Palpitations are a prominent and distressing symptom, particularly in the patient with preexisting heart disease. Proximal muscle weakness is common and is noted on climbing stairs or in getting up from a sitting position. Women may note their menses are becoming scanty and irregular. Extremely thyrotoxic (thyrotoxic storm) patients may have tachycardia, heart failure, psychosis, hyperpyrexia, and coma. 22

Differential Diagnosis

If the clinical history and examination do not provide pathognomonic clues to the etiology of the patient’s thyrotoxicosis, measurement of the radioactive iodine uptake (RAIU) is critical in the evaluation (Table 84–3). The normal 24-hour RAIU ranges from 10% to 30% with some regional variation that is due to differences in iodine intake. An elevated RAIU indicates true hyperthyroidism, that is, the patient’s thyroid gland is actively overproducing T 4 , T 3 , or both. Conversely, a low RAIU in the absence of iodine excess indicates that high levels of thyroid hormone are not a consequence of thyroid gland hyperfunction but are likely due to thyroiditis or hormone ingestion. The importance of differentiating true hyperthyroidism from other causes of thyrotoxicosis lies in the widely different prognosis and treatment of the diseases in these two categories. Therapy of thyrotoxicosis associated with thyroid hyperfunction is mainly directed at decreasing the rate of thyroid hormone synthesis, secretion, or both. Such measures are ineffective in treating thyrotoxicosis that is not the result of true hyperthyroidism, because hormone synthesis and regulated hormone secretion are already at a minimum.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH ELEVATED RAIU

TSH-Induced Hyperthyroidism

To better understand these syndromes, we must first review TSH biosynthesis and secretion. TSH is synthesized in the anterior pituitary as separate α- and β-subunit precursors. The α subunits from luteinizing hormone (LH), follicle-stimulating hormone (FSH), human chorionic gonadotropin (hCG), and TSH are similar, whereas the β subunits are unique and confer immunologic and biologic specificity. Free β subunits are devoid of receptor binding and biologic activity and require combination with an α subunit to express their activity. Criteria for the diagnosis of TSH-induced hyperthyroidism include (1) evidence of peripheral hypermetabolism, (2) diffuse thyroid gland enlargement, (3) elevated free thyroid hormone levels, and (4) elevated or inappropriately “normal” serum immunoreactive TSH concentrations. Because the pituitary gland is extremely sensitive to even minimal elevations of free T 4 , a “normal” or elevated TSH level in any thyrotoxic patient indicates the inappropriate production of TSH.

TSH-Secreting Pituitary Adenomas

TSH-secreting pituitary tumors occur sporadically and release biologically active hormone that is unresponsive to normal feedback control. 23 The mean age at diagnosis is around 40 years, with women being diagnosed more than men (8:7). These tumors may co-secrete prolactin or growth hormone; therefore the patients may present with amenorrhea/galactorrhea or signs of acromegaly. Most patients present with classic symptoms and signs of thyrotoxicosis. Visual-field defects may be present due to impingement of the optic chiasm by the tumor. Tumor growth and worsening visual-field defects have been reported following antithyroid therapy because lowering of thyroid hormone levels is associated with loss of feedback inhibition from high thyroid hormone levels.

Diagnosis of a TSH-secreting adenoma should be made by demonstrating lack of TSH response to TRH stimulation, inappropriate TSH levels, elevated α-subunit levels, and radiologic imaging; given the lack of routine availability of TRH, the other three criteria are essential. Note that some small tumors are not identified by MRI. Moreover, 10% of “normal” individuals may have incidental pituitary tumors or other benign focal lesions noted on pituitary imaging.

Transsphenoidal pituitary surgery is the treatment of choice for TSH-secreting adenomas. Pituitary gland irradiation is often given following surgery to prevent tumor recurrence. Bromocriptine and octreotide have been used to treat tumors, especially those that co-secrete prolactin.

Pituitary Resistance to Thyroid Hormone

Pituitary resistance to thyroid hormone (PRTH) refers to selective resistance of the pituitary thyrotrhops to thyroid hormone. 24 As nonpituitary tissues respond normally to thyroid hormone, patients experience the toxic peripheral effects of thyroid hormone excess. About twice as many women as men have been reported with this rare, probably familial syndrome. Multiple abnormalities have been reported in the initial 50 reported cases including schizophrenia (three patients), mental retardation (two patients), short fourth metacarpals (one patient), and Marfanoid habitus (one patient). About 90% of patients studied have an appropriate increase in TSH in response to TRH; conversely, the TSH will be suppressed by T 3 administration.

Patients with PRTH require treatment to reduce their elevated thyroid hormone levels. Determining the appropriate serum T 4 level is difficult because TSH cannot be used to evaluate adequacy of therapy. Any reduction in thyroid hormone carries the risk of inducing thyrotrhop hyperplasia. Ideally, agents that suppress TSH secretion could be used to treat these individuals. Glucocorticoids, dopaminergic drugs, somatostatin and its analogs, and thyroid hormone analogs with reduced metabolic
activity have all been tried; given the ability of retinoid X receptor ligands to inhibit TSH production, drugs like bexarotene may have therapeutic benefit in PRTH. 25

THYROID STIMULATORS OTHER THAN TSH

Graves’s Disease

Graves’s disease is an autoimmune syndrome that usually includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos, and less commonly pretibial myxedema and thyroid acropachy (Fig. 84–4).20,26,27 Graves’s disease is the most common cause of hyperthyroidism, with a prevalence estimated to be 3 per 1,000 population in the United States. Hyperthyroidism results from the action of thyroid-stimulating antibodies (TSAb), which are directed against the thyrotropin receptor on the surface of the thyroid cell.16,17 When these immunoglobulins bind to the receptor, they activate downstream G-protein signaling and adenylate cyclase in the same manner as TSH. Autoantibodies that react with orbital muscle and fibroblast tissue in the skin are responsible for the extrathyroidal manifestations of Graves’s disease, and these autoantibodies are encoded by the same germline genes that encode for other autoantibodies for striated muscle and thyroid peroxidase.28 Clinically, the extrathyroidal disorders may not appear at the same time that hyperthyroidism develops.

There is now compelling evidence that heredity predisposes the susceptible individual to development of clinically overt autoimmune thyroid disease in the setting of appropriate environmental and hormonal triggers. A role for gender in the emergence of Graves’s disease is suggested by the fact that hyperthyroidism is approximately eight times more common in women than men. Other lines of evidence support a role for heredity. First, there is a well-recognized clustering of Graves’s disease within some families. Twin studies in Graves’s disease have revealed that a monozygotic twin has a 35% likelihood of ultimately developing the disease compared with a 3% likelihood for a dizygotic twin, resulting in estimation that the 79% of the predisposition to Graves’s disease is genetic.29 Second, the occurrence of other autoimmune diseases, including Hashimoto’s thyroiditis, is also increased in families of patients with Graves’s disease. Third, several studies have demonstrated an increased frequency of certain human leukocyte antigens (HLAs) for patients with Graves’s disease. Differing HLA associations have been identified in the various ethnic groups studied. In whites, for example, the relative risk of Graves’s disease in carriers of the HLA-DR3 haplotype is between 2.5 and 5, whereas lesser associations have been reported for HLA-B8 and the HLA-DQA*0501 allele.30,31 As with other autoimmune conditions, certain polymorphisms of the T-cell immunoregulatory protein CTLA-4 have also been associated with Graves’s disease. Despite these statistical associations, however, even detailed molecular genetic linkage studies have failed to identify specific genes responsible for the disease.32

The thyroid gland is diffusely enlarged in the majority of patients and is commonly 40 to 60 g (two to three times the normal size). The surface of the gland is either smooth or bosselated, and the consistency varies from soft to firm. For patients with severe disease, a thrill may be felt and a systolic bruit may be heard over the gland, reflecting the increased intraglandular vascularity typical of hyperplasia. Whereas the presence of any of the extrathyroidal manifestations of this syndrome, including exophthalmos, thyroid acropachy, or pretibial myxedema, in a thyrotoxic patient is pathognomonic of Graves’s disease, most patients can be diagnosed on the basis of their history and examination of their diffuse goiter (see Fig. 84–4). An important clinical feature of Graves’s disease is the occurrence of spontaneous remissions, albeit uncommon. The abnormalities in TSAb production may decrease or disappear over time in many patients.

The results of laboratory tests in thyrotoxic Graves’s disease include an increase in the overall hormone production rate with a disproportionate increase in \( T_3 \) relative to \( T_4 \) (Table 84–4). In an occasional patient, the disproportionate overproduction of \( T_3 \) is
Human chorionic gonadotropin is a stimulator of the TSH receptor and may cause hyperthyroidism. The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α subunits and unique β subunits). In hyperthyroid patients with very high hCG levels, serum TSH may be inappropriately detectable due to the weak cross-reactivity of hCG in the radioimmunoassay for TSH. For patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 units/mL and always exceed 100 units/mL. The mean peak hCG level in normal pregnancy is 50 units/mL. On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity may be very substantial for patients with trophoblastic tumors, whose serum hCG concentrations may reach 2,000 units/mL.

### THYROID AUTONOMY

#### Toxic Adenoma

An autonomous thyroid nodule is a discrete thyroid mass whose function is independent of pituitary and TSH control. The prevalence of toxic adenoma ranges from about 2% to 9% of thyrotoxic patients, and depends on iodine availability and geographic location. Toxic adenomas arise from gain-of-function somatic mutations of the TSH receptor or, less commonly, the Gsα protein; more than a dozen TSH receptor mutations have been described. These nodules may be referred to as toxic adenomas, or “hot” nodules, because of their persistent uptake on a radioiodine thyroid scan, despite suppressed uptake in the surrounding nonnodular gland (Fig. 84–5). The amount of thyroid hormone produced by an

Trophoblastic Diseases

Human chorionic gonadotropin is a stimulator of the TSH receptor and may cause hyperthyroidism. The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α subunits and unique β subunits). In hyperthyroid patients with very high hCG levels, serum TSH may be inappropriately detectable due to the weak cross-reactivity of hCG in the radioimmunoassay for TSH. For patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 units/mL and always exceed 100 units/mL. The mean peak hCG level in normal pregnancy is 50 units/mL. On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity may be very substantial for patients with trophoblastic tumors, whose serum hCG concentrations may reach 2,000 units/mL.

### FIGURE 84–5.  Radioiodine thyroid scans. A. Normal or increased thyroid uptake of iodine-125 (¹²⁵I). (B) Thyroid with marked decrease in ¹²⁵I uptake in a large palpable mass. C. Increased ¹²⁵I uptake isolated to a single nodule, the “hot nodule.” D. Decreased thyroid ¹²⁵I uptake in an isolated region, the “cold nodule.” (Reproduced with permission from Molina PE. Endocrine Physiology, 2nd ed. New York: McGraw-Hill, 2006:90. Images courtesy of Dr. Luis Linares, Memorial Medical Center, New Orleans, LA.)
autonomous nodule is mass related. Therefore, hyperthyroidism usually occurs with larger nodules (i.e., those >3 cm in diameter). Older patients (>60 years) are more likely (up to 60%) to be thyrotoxic from autonomous nodules than are younger patients (12%). There are many reports of isolated elevation of serum T₄ for patients with autonomously functioning nodules. Therefore, if the T₄ level is normal, a T₃ level must be measured to rule out T₃ toxicity. If autonomous function is suspected but the TSH is normal, the diagnosis can be confirmed by a failure of the autonomous nodule to decrease its iodine uptake during exogenous T₄ administration sufficient to suppress TSH. Surgical resection, thionamides, percutaneous ethanol injection, and radioactive iodine (RAI) ablation are treatment options, but since thionamides do not halt the proliferative process in the nodule, definitive therapies are recommended. Ethanol ablation may be associated with pain and damage to surrounding extrathyroidal tissues, limiting its acceptance in the United States. It has been hypothesized that sublethal radiation doses received by the surrounding nonnodular thyroid tissue during RAI therapy of toxic nodules may lead to induction of thyroid cancer, and excess thyroid cancer mortality has recently been associated with RAI therapy of toxic nodular disease. Thus, an autonomously functioning nodule, if not large enough to cause thyrotoxicosis, can often be observed conservatively without therapy.

**Multinodular Goiters**

In multinodular goiters (MNGs; Plummer disease), follicles with autonomous function coexist with normal or even nonfunctioning follicles. The pathogenesis of MNG is thought to be similar to that of toxic adenoma: diffuse hyperplasia caused by goitrogenic stimuli, leading to mutations and clonal expansion of benign neoplasms. The functional status of the nodule(s) depends upon the nature of the underlying mutations, whether activating such as TSH receptor mutations or inhibitory such as ras mutations. Thyrotoxicosis in a MNG occurs when a sufficient mass of autonomous follicles generates enough thyroid hormone to exceed the needs of the patient. It is not surprising that this type of hyperthyroidism develops insidiously over a period of several years and predominantly affects older individuals with long-standing goiters. The patient’s complaints of weight loss, depression, anxiety, and insomnia may be attributed to old age. Any unexplained chronic illness in an elderly patient presenting with a MNG calls for the exclusion of hidden thyrotoxicosis. Third-generation TSH assays and T₃ suppression testing may be useful in detecting subclinical hyperthyroidism.

A thyroid scan will show patchy areas of autonomously functioning thyroid tissue intermixed with hypofunctioning areas. When the patient is euthyroid, therapy is based upon the need to reduce goiter size due to mass-related symptoms such as dysphagia. Doses of thyroid hormone sufficient to suppress TSH levels may slow goiter growth or cause some degree of shrinkage, but in general, suppression therapy for nodular disease is inadequate to address mass effect. The preferred treatment for toxic MNG is RAI or surgery. Surgery is usually selected for younger patients and patients in whom large goiters impinge on vital organs. Alternatively, percutaneous injection of 95% ethanol has also been used to destroy single or multinodular adenomas with a 5-year success rate approaching 80%.

**CAUSES OF THYROTOXICOSIS ASSOCIATED WITH SUPPRESSED RAIU**

**Inflammatory Thyroid Disease**

**Subacute Thyroiditis** Painful subacute (granulomatous or deQuervain) thyroiditis often develops after a viral syndrome, but rarely has a specific virus been identified in thyroid parenchyma. A genetic predisposition exists, with markedly higher risk for developing subacute thyroiditis for patients with HLA-Bw35. Systemic symptoms often accompany the syndrome, including fever, malaise, and myalgia, in addition to those symptoms due to thyrotoxicosis. Typically, patients complain of severe pain in the thyroid region, which often extends to the ear on the affected side. With time, the pain may migrate from one side of the gland to the other. On physical examination, the thyroid gland is firm and exquisitely tender. Signs of thyrotoxicosis are present.

Thyroid function tests typically run a triphasic course. Initially, serum thyroxine levels are elevated due to release of preformed thyroid hormone from disrupted follicles. The 24-hour RAIU during this time is less than 2% due to thyroid inflammation and TSH suppression by the elevated thyroxine level. As the disease progresses, intrathyroidal hormone stores are depleted, and the patient may become mildly hypothyroid with an appropriately elevated TSH level. During the recovery phase, thyroid hormone stores are replenished, and serum TSH concentration gradually returns to normal. Recovery is generally complete within 2 to 6 months. Most patients remain euthyroid, and recurrences of painful thyroiditis are extremely rare. The patient with painful thyroiditis should be reassured that the disease is self-limited and is unlikely to recur. Thyrotoxic symptoms may be relieved with β-blockers. Aspirin (650 mg orally every 6 hours) will usually relieve the pain. Occasionally, prednisone (20 mg orally three times a day) must be used to suppress the inflammatory process. Antithyroid drugs are not indicated because they do not decrease the release of preformed thyroid hormone.

**Painless Thyroiditis** Since its description in 1975, painless (silent, lymphocytic) thyroiditis has been recognized as a common cause of thyrotoxicosis and may represent up to 15% of cases of thyrotoxicosis in North America. In the setting of development of lymphocytic thyroiditis during the first 12 months after the end of pregnancy, the condition is also called postpartum thyroiditis. The etiology is not fully understood and may be heterogeneous, but evidence indicates that autoimmunity underlies most cases. There is an increased frequency of HLA-DR3 and DR5 in patients with painless thyroiditis; nonendocrine autoimmune diseases are also more common. Histologically, diffuse lymphocytic infiltration is generally identified. The triphasic course of this illness mimics that of subacute thyroiditis. Most patients present with mild thyrotoxic symptoms. Lid retraction and lid lag are present, but exophthalmos is absent. The thyroid gland may be diffusely enlarged, but thyroid tenderness is absent.

The 24-hour RAIU will typically be suppressed to less than 2% during the thyrotoxic phase of painless thyroiditis. Antithyroglobulin and antithyroid peroxidase antibody levels are elevated in more than 50% of patients. Patients with mild hyperthyroidism and painless thyroiditis should be reassured that they have a self-limited disease, although patients with postpartum thyroiditis may experience recurrence of the disease with subsequent pregnancies. As with other thyroiditis syndromes, adrenergic symptoms may be ameliorated with propranolol or metoprolol. Antithyroid drugs, which inhibit new hormone synthesis, are not indicated because they do not decrease the release of preformed thyroid hormone.

**Ectopic Thyroid Tissue**

**Struma Ovarii** Struma ovarii is a teratoma of the ovary that contains differentiated thyroid follicular cells and is capable of making thyroid hormone. This extremely rare cause of thyrotoxicosis is suggested by the absence of thyroid enlargement in a thyrotoxic patient with a suppressed RAIU in the neck and no findings to suggest thyroiditis. The diagnosis is established by localizing
functioning thyroid tissue in the ovary with whole-body radioactive iodine ($^{131}$I) scanning. Interestingly, struma ovarii without associated hyperthyroidism is much more common than struma ovarii associated with hyperthyroidism. Because the tissue is neoplastic and potentially malignant, combined surgical and radiiodine treatment of malignant struma ovarii for both monitoring and therapy of relapse is the recommended treatment.

**Thyroid Cancer** In widely metastatic differentiated papillary or follicular carcinomas with relatively well-preserved function, sufficient thyroid hormone can be synthesized and secreted to produce thyrotoxicosis. In most instances, a previous diagnosis of thyroid malignancy has been made. The diagnosis can be confirmed by whole-body $^{131}$I scanning. Treatment with $^{131}$I is generally effective at ablating functioning thyroid metastases.

**Exogenous Sources of Thyroid Hormone**

*Thyrotoxicosis factitia* is produced by the ingestion of exogenous thyroid hormone. Obesity is the most common nonthyroidal disorder for which thyroid hormone is inappropriately used, but thyroid hormone has been used for almost every conceivable problem from menstrual irregularities and infertility to hypercholesterolemia and baldness. There is little evidence to suggest that treatment with thyroid hormone is beneficial for such conditions in euthyroid individuals. Obviously, thyrotoxicosis factitia can also occur when too large a dose of thyroid hormone is employed for conditions in which it is likely to be beneficial, such as differentiated thyroid carcinoma. Rarely, thyrotoxicosis factitia is caused by the purposeful and secretive ingestion of thyroid hormone by disturbed patients (usually with a medical background) who wish to obtain attention or lose weight.

Thyrotoxicosis factitia should be suspected in a thyrotoxic patient without evidence of increased hormone production, thyroidal inflammation, or ectopic thyroid tissue. The RAIU uptake is at low levels because the patient’s thyroid gland function is suppressed by the exogenous thyroid hormone. Measurement of plasma thyroglobulin (TG) is a valuable laboratory aid in the diagnosis of thyrotoxicosis factitia. TG is normally secreted in small amounts by the thyroid gland; however, when thyroid hormone is taken orally, TG levels tend to be lower than the normal range. In other entities characterized by a low RAIU, such as thyroiditis, leakage of preformed thyroid hormone results in elevated TG levels. If a history of thyroid hormone ingestion is elicited or deduced, exogenous thyroid hormone should be withheld for between 4 and 6 weeks, and thyroid function tests repeated to document that the euthyroid state has been restored. Rarely, thyroid hormone analogues or metabolites may be the drug of abuse, specific detection of which may be difficult with standard thyroid hormone assays. For example, tiratricol [triiodothyroacetic acid (TRIAC)], an endogenous metabolite of $T_3$ that has been used for weight loss and paradoxically by body builders, will suppress TSH at high enough doses and may cross-react in many T3 immunoassays; thus, thyrotoxicosis factitia due to tiratricol abuse may be misinterpreted as $T_3$ toxicosis.

Amiodarone may induce thyrotoxicosis (2% to 3% of patients), overt hypothyroidism (5% of patients), subclinical hypothyroidism (25% of patients), or euthyroid hyperthyroxinemia, depending upon the underlying thyroid pathology or lack thereof. Because amiodarone contains 37% iodine by weight, approximately 6 mg/day of iodine is released for each 200 mg of amiodarone, 1,000 times greater than the recommended daily amount of iodine of 200 mcg/day. As a result of this iodine overload, iodine-exacerbated thyroid dysfunction commonly occurs among those patients with preexisting thyroid disease: thyrotoxicosis in patients with hyperthyroidism or euthyroid nodular autonomy and hypothyroidism in patients with autoimmune thyroid disease. In contrast to hyperthyroidism with increased synthesis of thyroid hormone induced by amiodarone (type I), destructive thyroiditis with loss of TG and thyroid hormones also occurs (type II), typically among individuals with otherwise normal glands. The two types of amiodarone-induced thyrotoxicosis may be differentiated using color flow Doppler ultrasonography. Such distinction is critically important, given the therapeutic implications of the two syndromes: type I amiodarone-induced hyperthyroidism responds somewhat to thionamides, whereas type II may respond to glucocorticoids or iopanoic acid.

Unfortunately, however, the latter agent is no longer available. Obviously, RAI therapy is inappropriate in type I due to the drug-induced iodine excess, and in type II due to lack of increased hormone synthesis. The manifestations of amiodarone-induced thyrotoxicosis may be atypical symptoms such as ventricular tachycardia and exacerbation of underlying chronic obstructive pulmonary disease, both of which are even more significant given the severe underlying cardiac pathology that led to the use of the drug in the first place. Amiodarone also directly interferes with type I $5’$-deiodinase, leading to reduced conversion of $T_4$ to $T_3$ and hyperthyroxinemia without thyrotoxicosis.

---

**TREATMENT**

### Hyperthyroidism

#### DESIRED OUTCOMES

Three common treatment modalities are used in the management of hyperthyroidism: surgery, antithyroid medications, and radioactive iodine (RAI) (Table 84–5). The overall therapeutic objectives are to eliminate the excess thyroid hormone and minimize the symptoms and long-term consequences of hyperthyroidism. Therapy must be individualized based on the type and severity of hyperthyroidism, patient age and gender, existence of nonthyroidal conditions, and response to previous therapy. Clinical guidelines for the treatment of hyperthyroidism have been published by various groups.

#### NONPHARMACOLOGIC THERAPY

Surgical removal of the hypersecreting thyroid gland became feasible in 1923 when Plummer discovered that iodine reduced the gland’s vascularity, making this definitive procedure possible. Surgery should be considered for patients with a large thyroid gland (>80 g), severe ophthalmopathy, and a lack of remission on antithyroid drug treatment. In case of cosmetic or pressure symptoms, the choice in MNG stands between surgery, which is still the first choice, and radioactive iodine if uptake is adequate (hot). In addition to surgery, the solitary nodule, whether hot or cold, can be treated with percutaneous ethanol injection therapy. If hot, radiiodine is the therapy of choice. Traditional preparation of the patient for thyroidectomy includes propylthiouracil (PTU) or methimazole (MMI) until the patient is biochemically euthyroid (usually 6 to 8 weeks), followed by the addition of iodides (500 mg/day) for 10 to 14 days before surgery to decrease the vascularity of the gland. Iodine supplementation in iodine-deficient areas of the country may lead to a greater reduction in remnant volume in nontoxic goiter. Propranolol for several weeks preoperatively and 7 to 10 days after surgery has also been used to maintain a pulse rate of less than 90 beats/min. Combined pretreatment with propranolol and 10 to 14 days of potassium iodide also has been advocated.
The overall morbidity rate with surgery is 2.7%. Hyperthyroidism persists or recurs in 0.6% to 17.9% of patients after thyroidectomy for Graves’s disease and is more common in children. The most common complications of surgery include hypothyroidism (up to about 49%), hypoparathyroidism (up to 3.9%), and vocal cord abnormalities (up to 5.4%). The frequent occurrence of hypothyroidism following surgery requires periodic follow-up for identification and treatment of these patients. 24,63

### PHARMACOLOGIC THERAPY

#### Antithyroid Medications

**Thiourea Drugs**  Four drugs within this category, PTU and MMI, are approved for the treatment of hyperthyroidism in the United States. 64 They are classified as thioureylenes (thionamides), which incorporate an N—C—S —— N group into their ring structures.

**Mechanism of action.** PTU and MMI share several mechanisms to inhibit the biosynthesis of thyroid hormone. 65 These drugs serve as preferential substrates for the iodinating intermediate of thyroid peroxidase and divert iodine away from potential iodination sites in TG. This prevents subsequent incorporation of iodine into iodothyrosines and ultimately iodothyronine (“organification”). Second, they inhibit coupling of monoiodotyrosine and diiodotyrosine to form T₄ and T₃. The coupling reaction may be more sensitive to these drugs than the iodination reaction. Experimentally, these drugs exhibit immunosuppressive effects, although the clinical relevance of this finding is unclear. For patients with Graves’s disease, antithyroid drug treatment has been associated with lower TSAb titers and restoration of normal suppressor T-cell function. However, perchlorate, which has a different mechanism of action, also decreases TSAbs, suggesting that normalization of the thyroid hormone level may itself improve the abnormal immune function.

**Pharmacokinetics.** Both antithyroid drugs are well absorbed (80% to 95%) from the gastrointestinal tract, with peak serum concentrations about 1 hour after ingestion. The plasma half-life ranges of PTU and MMI are 1 to 2.5 hours and 6 to 9 hours, respectively, and are not appreciably affected by thyroid status. Urinary excretion is about 35% for PTU and less than 10% for MMI. These drugs are actively concentrated in the thyroid gland, which may account for the disparity between their relatively short plasma half-lives and the effectiveness of once daily dosing regimens even with PTU. Approximately 60% to 80% of PTU is bound to plasma albumin, whereas MMI is not protein bound. Methimazole readily crosses the placenta and appears in breast milk. Older studies suggested that PTU crosses the placental membranes only one tenth as well as MMI; however, these studies were done in the course of therapeutic abortion early in pregnancy. Newer studies show little difference between fetal concentrations of PTU and MMI, and both are associated with elevated TSH in about 20% and low T₄ in about 7% of the fetuses. 67

**Dosing and monitoring.** PTU is available as 50 mg tablets, and MMI as 5 and 10 mg tablets. MMI is approximately 10 times more potent than PTU. Initial therapy with PTU ranges from 300 to 600 mg daily, usually in three or four divided doses. PTU is given in two or three divided doses totaling 30 to 60 mg/day. Although the traditional recommendation is for divided doses, evidence exists that both drugs can be given as single daily doses. Patients with severe hyperthyroidism may require larger initial doses, and some may respond better at these larger doses if the dose is divided. The maximal blocking doses of PTU and MMI are 1,200 and 120 mg daily, respectively. Once the intrathyroidal pool of thyroid hormone is reduced and new hormone synthesis is sufficiently blocked, clinical improvement should ensue. Usually within 4 to 8 weeks of initiating therapy, symptoms will diminish and circulating thyroid hormone levels will return to normal. At this time the tapering regimen can be started. Changes in dose for each drug should be made on a monthly basis, because the endogenously produced T₄ will reach a new steady-state concentration in this interval. Typical ranges of daily maintenance doses for PTU and MMI are 50 to 300 mg and 5 to 30 mg, respectively.

If the objective of therapy is to induce a long-term remission, the patient should remain on continuous antithyroid drug therapy for 12 to 24 months. Antithyroid drug therapy induces permanent remission rates of 10% to 98%, with an overall average of about 40% to 50%. 65 This is much higher than the remission rate seen with propranolol alone, which is reported to range from 22% to 36%. Patient characteristics for a favorable outcome include older patients (>40 years), low ratio of T₄ to T₃ (<20), a small goiter (<50 g), short duration of disease (<6 months), no previous history of relapse with antithyroid drugs, duration of therapy 1 to 2 years or longer, and low TSAb titers at baseline or a reduction with treatment. 40 It is important that patients be followed every 6 to 12 months after remission occurs.

**Porcine Thyroid Extract**

Porcine thyroid extract contains T₄ and T₃, and is often used as an alternative to synthetic antithyroid drugs. A trial of porcine thyroid extract may be considered if the patient is unable to tolerate antithyroid drugs. It is important to monitor the patient closely for signs of hyperthyroidism, as porcine thyroid extract can cause a rapid increase in thyroid hormone levels. If a patient is on porcine thyroid extract and develops signs of hyperthyroidism, it is important to taper the dose immediately to prevent exacerbation of symptoms.

**Radioactive iodine (¹³¹I)**

Radioactive iodine is used to treat hyperthyroidism by destroying the thyroid gland. It is often used as a last resort after other treatments have failed. The patient must be euthyroid before radioactive iodine therapy can be administered, and the patient must be well hydrated to avoid toxic effects. The patient is usually admitted to the hospital for a few days before the treatment to ensure proper hydration and to monitor for adverse effects. The patient is also monitored after the treatment to ensure that the thyroid gland is adequately destroyed.

**Thyroid Implants**

Thyroid implants are used to replace missing thyroid tissue. They are usually made from porcine thyroid tissue that has been treated to remove any abnormal thyroid function. The implants are implanted under the skin, and the patient is usually euthyroid before the procedure. The patient is monitored after the procedure to ensure that the thyroid gland is adequately replaced.

**Thyroidectomy**

Thyroidectomy is used to treat hyperthyroidism by removing the thyroid gland. It is usually performed only as a last resort after other treatments have failed. The patient must be euthyroid before the procedure to avoid complications. The patient is usually admitted to the hospital for a few days before the procedure to ensure proper hydration and to monitor for adverse effects. The patient is also monitored after the procedure to ensure that the thyroid gland is adequately removed.

**Antithyroid Medications**

Antithyroid medications are used to treat hyperthyroidism by inhibiting the production of thyroid hormone. They are usually used as the first-line treatment for hyperthyroidism and are often used in combination with radioactive iodine therapy. The most commonly used antithyroid medications are propylthiouracil (PTU) and methimazole (MMI).

**Thioureagenous Hormones**

Thioureagenous hormones are used to treat hyperthyroidism by inhibiting the production of thyroid hormone. They are usually used as the first-line treatment for hyperthyroidism and are often used in combination with radioactive iodine therapy. The most commonly used thioureagenous hormones are propylthiouracil (PTU) and methimazole (MMI).

**Radioactive Iodine**

Radioactive iodine is used to treat hyperthyroidism by destroying the thyroid gland. It is often used as a last resort after other treatments have failed. The patient must be euthyroid before radioactive iodine therapy can be administered, and the patient must be well hydrated to avoid toxic effects. The patient is usually admitted to the hospital for a few days before the treatment to ensure proper hydration and to monitor for adverse effects. The patient is also monitored after the treatment to ensure that the thyroid gland is adequately destroyed.

**Thyroid Implants**

Thyroid implants are used to replace missing thyroid tissue. They are usually made from porcine thyroid tissue that has been treated to remove any abnormal thyroid function. The implants are implanted under the skin, and the patient is usually euthyroid before the procedure. The patient is monitored after the procedure to ensure that the thyroid gland is adequately replaced.

**Thyroidectomy**

Thyroidectomy is used to treat hyperthyroidism by removing the thyroid gland. It is usually performed only as a last resort after other treatments have failed. The patient must be euthyroid before the procedure to avoid complications. The patient is usually admitted to the hospital for a few days before the procedure to ensure proper hydration and to monitor for adverse effects. The patient is also monitored after the procedure to ensure that the thyroid gland is adequately removed.
Iodide was the first form of drug therapy for Graves’s disease. It is effective in clearing the gland of stored hormone, thereby preventing the release of thyroid hormones. However, it is not commonly used as a sole agent due to its side effects, which include myalgias, arthralgias, and lupus-like syndromes. The recurrence rate seen for patients treated with antithyroid drugs alone is 30% to 50%, whereas major adverse effects occur in 1.5% to 4.6% of patients receiving these drugs. 

Adverse effects. Minor adverse reactions to PTU and MMI have an overall incidence of 5% to 25% depending on the dose and the drug, whereas major adverse effects occur in 1% to 4% of patients receiving these drugs. Minor reactions include gastrointestinal intolerance, which is also seen with PTU administration. Gastrointestinal intolerance is also reported to occur in 4% to 5% of patients. Patients receiving interferon products for hepatitis C or other disorders may develop hyper- or hypothyroidism along with liver enzyme abnormalities. Hypoprotrombinemia is a rare complication of thionamide therapy. Patients who have experienced a major adverse reaction to one thioamide drug should not be converted to the alternate drug because of cross-sensitivity.

Older reports suggested that congenital skin defects (aplasia cutis) may be caused by MMI and carbimazole, although a registry review from the Netherlands could not find an association between maternal use of these drugs and skin defects. However, more recently, several serious congenital malformations including tracheoesophageal fistulas and choanal atresia have been observed with MMI and carbimazole but not PTU use during pregnancy. Thus, in the past, PTU was considered the drug of choice throughout pregnancy for women with hyperthyroidism, because of concerns about the possible teratogenic effects of MMI. However, currently heightened concerns about the greater hepatotoxicity of PTU than MMI have led to the recommendation that PTU no longer be considered a first-line drug, except during the first trimester of pregnancy.

Hepatotoxicity can be seen with both MMI and PTU with a prevalence of approximately 1.3%. In mice, MMI undergoes epoxidation of the C-4,5 double bond by cytochrome P450 enzymes, and after being hydrolyzed, the resulting epoxide is decomposed to form N-methylthiourea, a proximate toxicant. At moderate doses, some authors have found that initial enzyme elevations eventually normalize in most patients with continued therapy. PTU-induced subclinical liver injury is common and is usually transient and asymptomatic.

Thus, it has generally been thought that therapy with PTU may be continued with caution in the absence of symptoms and hyperbilirubinemia. However, a 1997 literature review documented 49 cases of hepatotoxicity. Twenty-eight cases were associated with PTU use, and 21 cases were associated with MMI use. The hepatotoxicity was associated with seven deaths and three deaths in the PTU and MMI groups, respectively. There did not appear to be a relationship between the dose or duration of thionamide treatment and outcome. During the past 20 years of PTU use in the United States, 22 adults developed severe hepatotoxicity leading to nine deaths and five liver transplants. The risk of this complication was greater in children (1:2,000) than in adults (1:10,000). In light of such evidence, it was recommended by the American Thyroid Association and the United States and the Food and Drug Administration that PTU not be considered as first-line therapy in either adults or children. One of three exceptions includes the first trimester of pregnancy, when the risk of MMI-induced embryopathy may exceed that of PTU-induced hepatotoxicity.

Iodides Iodide was the first form of drug therapy for Graves’s disease. Its mechanism of action is to acutely block thyroid hormone release, inhibit thyroid hormone biosynthesis by interfering with intrathyroidal iodide utilization (the Wolff-Chaikoff effect), and decrease the size and vascularity of the gland. This early inhibitory effect provides symptom improvement within 2 to 7 days of initiating therapy, and serum T₄ and T₃ concentrations may be reduced for a few weeks. Despite the reduced release of T₄ and T₃, thyroid hormone synthesis continues at an accelerated rate, resulting in a gland rich in stored hormones. The normal and hyperfunctioning thyroid soon escapes from this inhibitory effect within 1 to 2 weeks by decreasing the active transfer of iodide into the gland. Iodides are often used as adjunctive therapy to prepare a patient with Graves’s disease for surgery, to acutely inhibit thyroid hormone release and quickly attain the euthyroid state in severely thyrotoxic patients with cardiac decompensation, or to inhibit thyroid hormone release following radioactive iodine therapy. However, large doses of iodine...
may exacerbate hyperthyroidism or indeed precipitate hyperthyroidism in some previously euthyroid individuals (Jod-Basedow disease). This Jod-Basedow phenomenon is most common in iodine-deficient areas, particularly for patients with preexisting nontoxic goiter. Iodide is contraindicated in toxic MNG.

Potassium iodide is available either as a saturated solution (SSKI), which contains 38 mg of iodide per drop, or as Lugol solution, which contains 6.3 mg of iodide per drop. The typical starting dose of SSKI is 3 to 10 drops daily (120 to 400 mg) in water or juice. There is no documented advantage to using doses in excess of 6 to 8 mg/day. When used to prepare a patient for surgery, it should be administered 7 to 14 days preoperatively. As an adjunct to RAI, SSKI should not be used before, but rather 3 to 7 days after RAI treatment, so that the radioactive iodide can concentrate in the thyroid. The most frequent toxic effect with iodide therapy is hypersensitivity reactions (skin rashes, drug fever, rhinitis, and conjunctivitis); salivary gland swelling; “iodism” (metallic taste, burning mouth and throat, sore teeth and gums, symptoms of a head cold, and sometimes stomach upset and diarrhea); and gynecomastia.

Other compounds containing organic iodide have also been used therapeutically for hyperthyroidism. These include various radiologic contrast media that share a triiodo- and monoaminobenzene ring with a propionic acid chain (e.g., iopanoic acid and sodium iopodate). The effect of these compounds is a result of the iodine content inhibiting thyroid hormone release as well as competitive inhibition of 5′-monodeiodinase conversion related to their structures, which resemble thyroid analogs. Unfortunately, these extremely useful agents are no longer available in the United States.

Adrenergic Blockers Because many of the manifestations of hyperthyroidism are mediated by β-adrenergic receptors, β-blockers (especially propranolol) have been used widely to ameliorate thyrotoxic symptoms such as palpitations, anxiety, tremor, and heat intolerance. Although β-blockers are quite effective for symptom control, they have no effect on the urinary excretion of calcium, phosphorus, hydroxyproline, creatinine, or various amino acids, suggesting a lack of effect on peripheral thyrotoxicosis and protein metabolism. Furthermore, β-blockers do not reduce TSAb nor prevent thyroid storm. Propranolol and nadolol partially block the conversion of T4 to T3, but this contribution to the overall therapeutic effect is small in magnitude. Inhibition of conversion of T4 to T3 is mediated by β-propranolol, which is devoid of β-blocking activity, and l-propranolol, which is responsible for the antiadrenergic effects, has little effect on the conversion.

β-Blockers are usually used as adjunctive therapy with antithyroid drugs, RAI, or iodides when treating Graves’s disease or toxic nodules; in preparation for surgery; or in thyroid storm. The only conditions for which β-blockers are primary therapy for thyrotoxicosis are those associated with thyroiditis. The dose of propranolol required to relieve adrenergic symptoms is variable, but an initial dose of 20 to 40 mg four times daily is effective (heart rate <90 beats/min) for most patients. Younger or more severely toxic patients may require as much as 240 to 480 mg/day because there appears to be an increased clearance rate for these patients. β-Blockers are contraindicated for patients with decompensated heart failure unless it is caused solely by tachycardia (high output). Nonselective agents and those lacking intrinsic sympathomimetic activity should be used with caution for patients with asthma and bronchospastic chronic obstructive lung disease. β-Blockers that are cardioselective and have intrinsic sympathomimetic activity may have a slight margin of safety in these situations. Other patients in whom contraindications exist are those with sinus bradycardia, those receiving monoamine oxidase inhibitors or tricyclic antidepressants, and those with spontaneous hypoglycemia. β-Blockers may also prolong gestation and labor during pregnancy. Other side effects include nausea, vomiting, anxiety, insomnia, light-headedness, bradycardia, and hematologic disturbances.

Antiadrenergic agents such as centrally acting sympatholytics and calcium channel antagonists may have some role in the symptomatic treatment of hyperthyroidism. These drugs might be useful when contraindications to β-blockade exist. When compared with nadolol 40 mg twice daily, clonidine 150 mcg twice daily reduced plasma catecholamines, whereas nadolol increased both epinephrine and norepinephrine after 1 week of treatment. Diltiazem 120 mg given every 8 hours reduced heart rate by 17%; fewer ventricular extrasystoles were noted after 10 days of therapy, and diltiazem has been shown to be comparable to propranolol in lowering heart rate and blood pressure.

Radioactive Iodine Although other radioisotopes have been used to ablate thyroid tissue, sodium iodide-131 (131I) is considered to be the agent of choice for Graves’s disease, toxic autonomous nodules, and toxic MNGs. RAI is administered as a colorless and tasteless liquid that is well absorbed and concentrates in the thyroid. Sodium iodide-131 is a β-and γ-emitter with a tissue penetration of 2 mm and a half-life of 8 days. Other organs take up 131I, but the thyroid gland is the only organ in which organification of the absorbed iodine takes place. Initially, RAI disrupts hormone synthesis by incorporating into thyroid hormones and TG. Over a period of weeks, follicles that have taken up RAI, and surrounding follicles develop evidence of cellular necrosis, breakdown of follicles, development of bizarre cell forms, nuclear pyknosis, and destruction of small vessels within the gland, leading to edema and fibrosis of the interstitial tissue. Predictors of successful treatment with RAI include higher ablative dose, female gender, lower free thyroxine levels at diagnosis, and absence of a palpable goiter. Pregnancy is an absolute contraindication to the use of RAI since radiation will be delivered to the fetal tissue, including the fetal thyroid.

β-Blockers may be given any time without compromising RAI therapy, accounting for their role as a mainstay of adjunctive therapy to RAI treatment. If iodides are administered, they should be given 3 to 7 days after RAI to prevent interference with the uptake of RAI in the thyroid gland. Because thyroid hormone levels will transiently increase following RAI treatment due to release of preformed thyroid hormone, patients with cardiac disease and elderly patients are often treated with thionamides prior to RAI ablation. Occasionally, for patients with underlying cardiac disease, it may be necessary to reinstitute antithyroid drug therapy following radioactive iodine ablation. The standard practice is to withdraw the thionamide 4 to 6 days prior to RAI treatment and to reinstitute it 4 days after therapy is concluded. Administering antithyroid drug therapy following RAI treatment may result in a higher rate of posttreatment recurrence or persistent hyperthyroidism. Pretreatment with PTU may lead to higher rates of treatment failure, but this does not appear to be the case with MMI pretreatment. Use of lithium, as adjunctive therapy to RAI therapy, has multiple benefits of increasing the cure rate, shortening the time to cure, and preventing posttherapy increase in thyroid hormone levels. Lithium is likely to achieve these effects by increasing RAI retention in the thyroid and inhibiting thyroid hormone release from the gland.

Corticosteroid administration will blunt and delay the rise in antibodies to the TSH receptor, TG, and thyroid peroxidase while reducing T3 and T4 concentrations following RAI. Bartalena and associates found no progression in ophthalmopathy for patients receiving prednisone after RAI compared with MMI (2% to 3% worsened) or no other treatment (5% with persistent worsening). Theoretically, if shared thyroidal and orbital antigen is involved in the pathogenesis of Graves’s ophthalmopathy, antigen released with RAI treatment could aggravate preexisting eye disease. Note also that thyroid ablation may decrease eye disease in the long
term by removing the source of antigen, but it is unclear if RAI differs from surgery or thionamide for the risk of worsening eye disease.\textsuperscript{91}

Destruction of the gland attenuates the hyperthyroid state, and hypothyroidism commonly occurs months to years following RAI.\textsuperscript{92} The goal of therapy is to destroy overactive thyroid cells, and a single dose of 4,000 to 8,000 rad results in a euthyroid state in 60% of patients at 6 months or less. The remaining 40% become euthyroid within 1 year, requiring two or more doses. It is advisable that a second dose of RAI be given 6 months after the first RAI treatment if the patient remains hyperthyroid. Variables that predict an unsuccessful outcome of RAI include gender (men are less likely to develop hypothyroidism), race, the size of the thyroid (euthyroidism is less likely in large glands), severity of disease, and perhaps a higher level of TSAb. In a recent study predictors of successful treatment with RAI included higher ablative dose, female gender, lower free thyroxine levels at diagnosis, and absence of a palpable goiter.\textsuperscript{93} The acute, short-term side effects of \textsuperscript{131}I therapy are minimal and include mild thyroidal tenderness and dysphagia. Concern over increased risk of mutations and congenital defects now appears to be unfounded because long-term follow-up studies have not revealed increased risk for these complications.\textsuperscript{94} In studies examining the risk of malignancies after RAI therapy, there seems to be a small but significant increase in the risk of cancer of the small bowel and thyroid.\textsuperscript{95} Although RAI is very effective in the treatment of hyperthyroidism, long-term follow-up from Great Britain suggests that among patients with hypothyroidism treated with RAI, mortality from all causes and mortality resulting from cardiovascular and cerebrovascular disease and fracture are increased.\textsuperscript{96}

A common approach to Graves’s hyperthyroidism is to administer a single dose of 5 to 15 mCi (80 to 200 μCi/g of tissue).\textsuperscript{97} The optimal method for determining \textsuperscript{131}I treatment doses for Graves’s hyperthyroidism is unknown, and techniques have varied from a fixed dose to more elaborate calculations based on gland size, iodine uptake, and iodine turnover. In a trial of 88 patients with Graves’s disease, no difference in outcome was seen among high or low, fixed or adjusted doses.\textsuperscript{98} Thyroid glands estimated to weigh >80 g may require larger doses of RAI. Larger doses are likely to induce hypothyroidism and are seldom given outside the United States due to the imposition of stringent safety restrictions. For example, in the United Kingdom, a nursery school teacher is advised to stay out of school for 3 weeks following a 15 mCi dose of \textsuperscript{131}I.\textsuperscript{99}

**EVALUATION OF THERAPEUTIC OUTCOMES: HYPERTHYROIDISM**

After therapy (surgery, thionamides, or RAI) for hyperthyroidism has been initiated, patients should be evaluated on a monthly basis until they reach a euthyroid condition. Clinical signs of continuing thyrotoxicosis (tachycardia, weight loss, and heat intolerance, among others) or the development of hypothyroidism (bradycardia, weight gain, and lethargy, among others) should be noted. \textbeta{}-Blockers can be used to control symptoms of thyrotoxicosis until the definitive treatment has returned the patient to a euthyroid state. Once thyroxine replacement is initiated, the goal is to maintain both the free thyroxine level and the TSH concentration in the normal range. Once a stable dose of thyroxine is identified, the patient may be followed up every 6 to 12 months.

Finally, a common, potentially confusing clinical situation should be mentioned. Why are the TSH concentrations suppressed for some patients who are clinically hypothyroid and who have a low free T\textsubscript{4} level? For patients with long-standing hyperthyroidism, the pituitary thyrotophs responsible for making TSH become atrophic. The average amount of time required for these cells to resume normal functioning is 6 to 8 weeks.\textsuperscript{98} Therefore, if a thyrotoxic patient has his or her free T\textsubscript{4} concentration lowered rapidly, before the thyrotophs resume normal function, a period of “transient central hypothyroidism” will be observed.

**SPECIAL CONDITIONS**

**Graves’s Disease And Pregnancy**\textsuperscript{99}

Inappropriate production of hCG is a cause of abnormal thyroid function tests during the first half of pregnancy, and hCG can cause either subclinical (normal T\textsubscript{4}, suppressed TSH) or overt hypothyroidism.\textsuperscript{100,101} This is because the homology of hCG and TSH leads to hCG-mediated stimulation through the TSH receptor. A recent study showed that at hCG concentrations greater than 400,000 international units/L, TSH levels were invariably suppressed and free thyroxine levels were generally above the normal range. Most patients with hCG greater than 200,000 international units/L did not have symptoms of hypothyroidism.\textsuperscript{102} The variability of the thyrotropic potency of hCG is believed to depend on its carbohydrate composition.

Hyperthyroidism during pregnancy is almost solely caused by Graves’s disease, with approximately 0.1% to 0.4% of pregnancies affected. Although the increased metabolic rate is usually well tolerated in pregnant women, two symptoms suggestive of hyperthyroidism during pregnancy are failure to gain weight despite good appetite and persistent tachycardia. There is no increase in maternal mortality or morbidity in well-controlled patients; however, postpartum thyroid storm has been reported in about 20% of untreated individuals. Fetal loss is also more common, due to the facts that spontaneous abortion and premature delivery are more common in untreated pregnant women, as are low-birth-weight infants and eclampsia. Transplacental passage of TSAb may occur, causing fetal as well as neonatal hyperothyroidism.\textsuperscript{103} An uncommon cause of hyperthyroidism is molar pregnancy; women present with a large-for-dates uterus and evacuation of the uterus is the preferred management approach.\textsuperscript{104}

Because RAI is contraindicated in pregnancy and surgery is usually not recommended (especially during the first trimester), antithyroid drug therapy is usually the treatment of choice. Methimazole readily crosses the placenta and appears in breast milk.

PTU is considered the drug of choice during the first trimester of pregnancy, with the lowest possible doses used to maintain the maternal T\textsubscript{4} level in the high-normal range.\textsuperscript{105,106} During this period the risk of MMI-associated embryopathy is believed to outweigh that of PTU-associated hepatotoxicity. To prevent fetal goiter and suppression of fetal thyroid function, PTU is usually prescribed in daily doses of 300 mg or less and tapered to 50 to 150 mg daily after 4 to 6 weeks. PTU doses of less than 200 mg daily are unlikely to produce fetal goiter.\textsuperscript{107} During the second and third trimesters, when the critical period of organogenesis is complete, MMI is thought to be the drug of choice because of the greater risk of hepatotoxicity with PTU.\textsuperscript{107} Thionamide doses should be adjusted to maintain free T\textsubscript{4} within 10% of the upper normal limit of the nonpregnant reference range.\textsuperscript{108} During the last trimester, TSAb s fall spontaneously, and some patients will go into remission so that antithyroid drug doses may be reduced. A rebound in maternal hyperthyroidism occurs in about 10% of women and may require more intensive treatment postpartum than in the last trimester of pregnancy.\textsuperscript{109} For example, a recent study of patients who were euthyroid after thionamide discontinuation and subsequently became pregnant showed a relative risk of a relapse of hyperthyroidism of 4.26 occurring 4 to 8 months after delivery.\textsuperscript{110}
Neonatal and Pediatric Hyperthyroidism

Following delivery, some babies of hyperthyroid mothers will be hyperthyroid due to placental transfer of TSAb, which stimulates thyroid hormone production in utero and postpartum.\textsuperscript{107,108} This is likely if the maternal TSAb titers were quite high. The disease is usually expressed 7 to 10 days postpartum and treatment with antithyroid drugs (PTU 5 to 10 mg/kg per day or MMI 0.5 to 1 mg/kg per day) may be needed for as long as 8 to 12 weeks until the antibody is cleared (immunoglobulin G half-life is about 2 weeks). Iodide (potassium iodide 1 drop per day or Lugol solution 1 to 3 drops per day) and sodium iodopate may be used for the first few days to acutely inhibit hormone release.

Childhood hyperthyroidism has classically been managed with either PTU or MMI. Long-term follow-up studies suggest that this form of therapy is quite acceptable, with 25% of a cohort experiencing remission every 2 years.\textsuperscript{109} Again, current recommendations suggest use of MMI as a first-line agent in both adults and children.

Thyroid Storm

Thyroid storm is a life-threatening medical emergency characterized by decompensated thyrotoxicosis, high fever (often $>$103°F), tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea.\textsuperscript{22} Although Graves’s disease and less commonly toxic nodular goiter are usually the underlying thyrotoxic pathology, at least two cases of subacute thyroiditis leading to thyroid storm have been reported.\textsuperscript{110–112} Precipitating factors for thyroid storm include infection, trauma, surgery, RAI treatment, and withdrawal from antithyroid drugs. Although the duration of clinical decompensation lasts for an average duration of 72 hours, symptoms may persist up to 8 days. With aggressive treatment, the mortality rate has been lowered to 20%. The following therapeutic measures should be instituted promptly: (1) suppression of thyroid hormone formation and secretion, (2) antiadrenergic therapy, (3) administration of corticosteroids, and (4) treatment of associated complications or coexisting factors that may have precipitated the storm. Specific agents used in thyroid storm are outlined in Table 84–6. PTU in large doses is generally the preferred thionamide because, in addition to interfering with the production of thyroid hormones, it also blocks the peripheral conversion of T\textsubscript{4} to T\textsubscript{3}. A theoretical advantage of MMI is that it has a longer duration of action. If patients are unable to take medications orally, the tablets can be crushed into suspension and instilled by gastric or rectal tube\textsuperscript{113} or given intravenously.\textsuperscript{114} Iodides, which rapidly block the release of preformed thyroid hormone, should be administered after PTU is initiated to inhibit iodide utilization by the overactive gland. If iodide is administered first, it could theoretically provide substrate for even higher levels of hormone.

Antiadrenergic therapy with the short-acting agent esmolol is preferred, both because it may be used in the patient with pulmonary disease or at risk for cardiac failure and because its effects may be rapidly reversed.\textsuperscript{115} Corticosteroids are generally recommended, although there is no convincing evidence of adrenocortical insufficiency in thyroid storm, and the benefits derived from steroids may be caused by their antipyretic action and their effect of stabilizing blood pressure.\textsuperscript{72} General supportive measures, including acetaminophen as an antipyretic (do not use aspirin or other nonsteroidal anti-inflammatory agents because they may displace bound thyroid hormone), fluid and electrolyte replacement, sedatives, digitalis, antiarrhythmics, insulin, and antibiotics should be given as indicated. Plasmapheresis and peritoneal dialysis have been used to remove excess hormone (and to remove thyroid-stimulating immunoglobulins in Graves’s disease) when the patient has not responded to more conservative measures, although these measures do not always work.\textsuperscript{116}

HYPOTHYROIDISM

Hypothyroidism is defined as the clinical and biochemical syndrome resulting from decreased thyroid hormone production.\textsuperscript{117} Overt hypothyroidism occurs in 1.5% to 2% of women and 0.2% of men, and its incidence increases with age. In the Third National Health and Nutrition Examination Survey, levels of serum TSH and total thyroxine (T\textsubscript{4}) were measured in a representative sample of adolescents and adults (age 12 or older). Among 16,533 people who neither were taking thyroid medication nor reported histories of thyroid disease, 3.9% had subclinical hypothyroidism (serum TSH $>$4.5 milli-international units/L and T\textsubscript{4} normal), and 0.2% had “clinically significant” hypothyroidism (TSH $>$4.5 milli-international units/L and T\textsubscript{4} $<$4.5 mcg/dL).\textsuperscript{21} The vast majority of patients have primary hypothyroidism due to thyroid gland failure due to chronic autoimmune thyroiditis. Special populations with higher risk of developing hypothyroidism include postpartum women, individuals with a family history of autoimmune thyroid disorders and patients with previous head and neck or thyroid irradiation or surgery, other autoimmune endocrine conditions (e.g., type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure), some other nonendocrine autoimmune disorders (e.g., celiac disease, vitiligo, pernicious anemia, Sjögren’s syndrome, and multiple sclerosis), primary pulmonary hypertension, and Down and Turner syndromes. Secondary hypothyroidism due to pituitary failure is uncommon but should be suspected in a patient with decreased levels of thyroxine and inappropriately normal or low TSH levels. Most patients with secondary hypothyroidism due to inadequate TSH production will have clinical signs of more generalized pituitary insufficiency, such as abnormal menses and decreased libido, or evidence of a pituitary adenoma, such as visual-field defects, galactorrhea, or acromegalic features, but isolated TSH deficiency can be congenital or acquired as a result of autoimmune hypophysitis.\textsuperscript{118} Generalized (peripheral and central) resistance to thyroid hormone is extremely rare.

Thyroid hormone is essential for normal growth and development during embryonic life. Uncorrected thyroid hormone deficiency during fetal and neonatal development results in mental retardation and/or cretinism. There is slowing of physical and mental activity, as well as of cardiovascular, gastrointestinal, and neuromuscular function.

A rise in the TSH level is the first evidence of primary hypothyroidism. Many patients will have a free T\textsubscript{4} level within the normal range (compensated hypothyroidism) and few, if any, symptoms of
Causes of Hypothyroidism

1316

SECTION 8

CLINICAL PRESENTATION OF HYPOTHYROIDISM

General
- Hypothyroidism can lead to a variety of end-organ effects with a wide range of disease severity, from entirely asymptomatic individuals to patients in coma with multisystem failure. In the adult, manifestations of hypothyroidism are varied and non-specific. In the child, thyroid hormone deficiency may manifest as growth or intellectual retardation.

Symptoms
- Common symptoms of hypothyroidism include dry skin, cold intolerance, weight gain, constipation, and weakness. Complaints of lethargy, depression, fatigue or loss of ambition and energy are also common but are less specific. Muscle cramps, myalgia, and stiffness are frequent complaints of hypothyroid patients. Menorrhagia and infertility may present commonly in women.

Signs
- Objective weakness is common, with proximal muscles being affected more than distal muscles. Slow relaxation of deep tendon reflexes is common. The most common signs of decreased levels of thyroid hormone include coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia. Speech is often slow as well as hoarse. Reversible neurologic syndromes such as carpal tunnel syndrome, polyneuropathy, and cerebellar dysfunction may also occur. Galactorrhea may be found in women.

Diagnosis
- In primary hypothyroidism, TSH serum concentration should be elevated. In secondary hypothyroidism, TSH levels may be within or below the reference range; when TSH bioactivity is altered, the levels reported by immunoassay may even be elevated.
- Free and/or total T4 and T3 serum concentrations should be low.
- Other tests
  - Antithyroid peroxidase antibodies and anti-TG antibodies are likely to be elevated in autoimmune thyroiditis.

Hypothyroidism occurs within 3 months to a year after 131 I therapy of radiation (radioiodine or external radiation) or surgery. Iatrogenic hypothyroidism follows exposure to excessive amounts of radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after 131 I therapy in most patients treated for Graves’s disease. Thereafter it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2,500 cGy for therapy of neck carcinoma also causes hypothyroidism. This effect is dose dependent, and more than 50% of patients who receive more than 4,000 cGy to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month.

Other Causes of Primary Hypothyroidism

Iatrogenic hypothyroidism follows exposure to excessive amounts of radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after 131 I therapy in most patients treated for Graves’s disease. Thereafter it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2,500 cGy for therapy of neck carcinoma also causes hypothyroidism. This effect is dose dependent, and more than 50% of patients who receive more than 4,000 cGy to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month.

CAUSES OF HYPOTHYROIDISM

Table 84–7 outlines the causes of hypothyroidism.

### Chronic Autoimmune Thyroiditis

Autoimmune thyroiditis (Hashimoto’s disease) is the most common cause of spontaneous hypothyroidism in the adult.119 Patients may present either with goitrous thyroid gland enlargement and mild hypothyroidism or with thyroid gland atrophy and more severe thyroid hormone deficiency. Both forms of autoimmune thyroiditis probably result from cell- and antibody-mediated thyroid injury. The bulk of evidence suggests that the presence of specific defects in suppressor T-lymphocyte function leads to the survival of a randomly mutating clone of helper T lymphocytes, which are directed against normally occurring antigens on the thyroid membrane. Once these T lymphocytes interact with thyroid membrane antigen, B lymphocytes are stimulated to produce thyroid antibodies.120

Antithyroid peroxidase (antimicrosomal) antibodies are present in virtually all patients with Hashimoto’s thyroiditis and appear to be directed against the enzyme thyroid peroxidase.121 These antibodies are capable of fixing complement and inducing cytotoxic changes in thyroid cells. Antibodies that are capable of stimulating thyroid growth through interaction with the TSH receptor may occasionally be found particularly in goitrous hypothyroidism; conversely, antibodies that inhibit the trophic effects of TSH are present in the atrophic type.

### Other Causes of Primary Hypothyroidism

Iodine deficiency, enzymatic defects within the thyroid gland, thyroid hypoplasia, and maternal ingestion of goitrogens during fetal development may cause cretinism. Early recognition and treatment of the resultant thyroid hormone deficiency is essential for optimal mental development.122,123 Large-scale neonatal screening programs in North America and Europe are now in place.124 The frequency of congenital hypothyroidism in North America and Europe is 1 per 3,500 to 4,000 live births. In the United States, there are racial differences in the incidence of congenital hypothyroidism, with whites being affected seven times as frequently as blacks.

In the adult, hypothyroidism may rarely be caused by iodine deficiency and goitrogens. Rarely, iodine ingestion in the form of expectorants can lead to hypothyroidism. In sensitive persons (particularly those with autoimmune thyroiditis), the iodide blocks the synthesis of thyroid hormone, leading to an increased secretion of TSH and thyroid enlargement. Thus, both iodine excess and iodine deficiency can cause decreased secretion of thyroid hormone.

### Causes of Secondary Hypothyroidism

**Pituitary Disease** TSH is required for normal thyroid secretion. Thyroid atrophy and decreased thyroid secretion follow pituitary failure. Pituitary insufficiency may be caused by destruction of

General Approach

Any of the commercially available thyroid preparations accomplish this goal (Table 84–8); however, levothyroxine (L-thyroxine, T₄) is considered to be drug of choice for treatment of hypothyroidism. Other commercially available thyroid preparations can be obtained but are not considered preferred therapy. Available thyroid preparations are synthetic (levothyroxine, liothyronine, and liothyrin) or natural (i.e. desiccated thyroid and TG) in origin. The availability of sensitive and specific assays for total and free hormone levels as well as TSH now allow definitive dose titration to allow adequate replacement without inadvertent overdose. The response of TSH to TRH had been advocated for use by some for “fine tuning” thyroid replacement, but this is not necessary if the third generation chemiluminometric assays for TSH, which have detection limits of about 0.01 milli-international units/L, are used. Moreover, TRH is no longer commercially available. Minimum clinical guidelines for the treatment of hypothyroidism have been published by the American Thyroid Association and the American Association of Clinical Endocrinologists.

Synthetic Thyroid Hormones

Levothyroxine (T₄; L-thyroxine) is the drug of choice for thyroid replacement and suppressive therapy because it is chemically stable, relatively inexpensive, and free of antigenicity and has uniform potency. Whereas T₄ and not T₃ is the biologically more active form of thyroid hormone, levothyroxine administration results in a pool of thyroid hormone that is readily and consistently converted to T₃; in this regard levothyroxine may be thought of as a prohormone. The ability of levothyroxine to achieve normal T₃ concentrations was illustrated in a study of recently athyreotic patients in whom levothyroxine monotherapy produced similar T₃ levels to those documented prior to the patient’s thyroidectomy. The half-life of levothyroxine is approximately 7 days. This long half-life is responsible for a stable pool of prohormone and the need for only once daily dosing with levothyroxine. Older studies with levothyroxine suggested that bioavailability was low and erratic; however, this product has been reformulated, and the average bioavailability is now approximately 80%. Different levothyroxine preparations contain different excipients such as dyes and fillers. The bioavailability of Synthroid, Levoxine, and

TREATMENT

Hypothyroidism

Pharmacologic Therapy

Desired Outcomes

The goals of therapy are to restore normal thyroid hormone concentrations in tissue, provide symptomatic relief, prevent neurologic deficits in newborns and children, and reverse the biochemical abnormalities of hypothyroidism.
generic levothyroxine preparations were compared in a blinded, randomized, four-way crossover trial.\textsuperscript{134} The study was sponsored by the manufacturers of Synthroid, who have challenged the authors’ conclusions that the levothyroxine preparations are bioequivalent and should be interchangeable for the majority of patients. However, because the relationship between \( T_4 \) concentration and TSH is not linear, very small changes in \( T_4 \) concentration can lead to substantial changes in TSH, which is a more accurate reflection of hormone replacement status. Currently, the Food and Drug Administration mandates that levothyroxine bioequivalency testing be done for normal volunteers (600 mcg in the fasted state) and three baseline free thyroxine concentrations be used to correct for endogenous \( T_3 \) production. Bioequivalency is based on the area under the curve (AUC) and maximum concentration (Cmax) of \( T_4 \) out to 48 hours. Approximately 70\% of the AUC is derived from endogenous production. TSH is not considered, and it is now very clear that \( T_3 \) is too insensitive as a measure of bioequivalency.\textsuperscript{135,136} To avoid over- and undertreatment, once a product is selected, therapeutic interchange should be discouraged. Currently, there are several levothyroxine products available, and a number of permutations for interchange are available considering that there are AB1, AB2, AB3, and AB4 products available since no reference listed drug is mandated in bioequivalency testing.

The time to maximal absorption of levothyroxine is about 2 hours and this should be considered when \( T_4 \) concentrations is determined. Ingestion of levothyroxine with food can impair its absorption.\textsuperscript{137} This can potentially affect the TSH concentration achieved if levothyroxine timing with respect to food is varied.\textsuperscript{138} Mucosal diseases such as sprue, diabetic diarrhea, and ileal bypass surgery can also reduce absorption. Cholestyramine, calcium carbonate, sucralose, aluminum hydroxide,\textsuperscript{139} ferrous sulfate,\textsuperscript{140} soybean formula,\textsuperscript{141} dietary fiber supplements,\textsuperscript{142} and espresso coffee\textsuperscript{143} may also impair the absorption of levothyroxine from the gastrointestinal tract. Acid suppression with histamine blockers and proton pump inhibitors may also reduce levothyroxine absorption.\textsuperscript{144} Drugs that increase nondeiodinative \( T_4 \) clearance include rifampin, cambazepine, and possibly phenytoin. Selenium deficiency and amiodarone may block the conversion of \( T_4 \) to \( T_3 \).

Liothyronine (\( T_3 \)) is chemically pure with known potency and has a shorter half-life of 1.5 days. Although it can be used diagnostically in the \( T_3 \)-suppression test, \( T_3 \) has some clinical disadvantages, including a higher incidence of cardiac adverse effects, higher cost, and difficulty in monitoring with conventional laboratory tests. Liotrix is a combination of synthetic \( T_3 \) and \( T_4 \) in a 4:1 ratio that attempts to mimic natural hormonal secretion. It is chemically stable and pure and has a predictable potency. The major limitations to this product are high cost and lack of therapeutic rationale, because most \( T_4 \) is peripherally converted from \( T_3 \). In addition, the ratio of \( T_3 \) to \( T_4 \) is much higher than the 14:1 molar ratio produced by the thyroid gland in humans.

Trials comparing levothyroxine alone to a combination of levothyroxine plus partial replacement with liothyronine (triiodothyronine) have generally shown that combinations of \( T_3 + T_4 \) are no better than \( T_4 \) alone.\textsuperscript{145,146} Over 10 such trials with varying designs have been performed to date. In one trial of combination therapy Clyde, et al.\textsuperscript{146} compared levothyroxine alone for treatment of primary hypothyroidism with combination therapy using levothyroxine plus liothyronine. These investigators demonstrated no beneficial changes in body weight, serum lipid levels, hypothyroid symptoms as measured by a health-related quality-of-life questionnaire, and standard measures of cognitive performance.\textsuperscript{146} Two metaanalyses have also suggested no benefits.\textsuperscript{147,148} However, a recent study, suggested that individuals harboring a specific deiodinase polymorphism may have a poorer psychological response to levothyroxine therapy and a better response to combination therapy with both \( T_3 \) and \( T_4 \).

### Natural Thyroid Hormones

Desiccated thyroid is derived from hog, beef, or sheep thyroid gland. The United States Pharmacopeia, 23th ed., requires Thyroid USP to contain 38 mcg (±15\%) of levothyroxine and 9 mcg (±10\%) of thyroglobulin for each 65 mg (1 grain) of the labeled content of TG. Thyroglobulin USP should contain 36 mcg (±15\%) of levothyroxine and 12 mcg (±10\%) of thyroglobulin for each 65 mg (1 grain) of the labeled content of TG. Not all generic brands may be bioequivalent, and switching among brands for patients stabilized on one product should be discouraged. Thyroid USP, as an animal protein–derived product, may be antigenic in allergic or sensitive patients. Even though desiccated thyroid is inexpensive, its limitations preclude it from being considered as a drug of choice for hypothyroid patients. TG is a purified hog-gland extract, but it has no clinical advantages and is not widely used.

#### Dosing and Monitoring

Recent studies suggest that the average maintenance dose of levothyroxine for most adults is about 125 mcg/day.\textsuperscript{117} The replacement dose of levothyroxine is affected by body weight. Estimates of weight-based doses for replacement in hypothyroid patients include 1.6 mcg/kg/day and 1.7 mcg/kg/day.\textsuperscript{149,150} There is, however, a wide range of replacement doses, necessitating individualized therapy and appropriate TSH monitoring to determine an adequate but not excessive dose.

In addition to alleviation of symptoms, the goal of treatment for patients with hypothyroidism is to maintain the patient’s TSH within the normal range. Some clinicians are of the opinion that the traditional reference range of approximately 0.5 to 4.5 milli-international units/L includes at its upper end some individuals who have unrecognized thyroid disease.\textsuperscript{151} Thus, some believe that the reference range should be modified downwards to 0.5 to 3.5 milli-international units/L or even 0.5 to 2.5 milli-international units/L.\textsuperscript{149,150} If this premise is accepted, both the TSH values that trigger levothyroxine treatment and the TSH treatment goal could potentially be altered. There are cogent arguments on both sides of the issue. Those who would suggest maintaining current reference ranges believe that changes would result in the treatment with thyroid hormone of many individuals who would not necessarily benefit from treatment.\textsuperscript{153} Those who favor narrowing the range suggest that additional patients would derive benefit from thyroid hormone treatment.\textsuperscript{154} TSH reference ranges also differ for different populations, such as those who are pregnant, specific ethnic groups, and older individuals.

The required dose of levothyroxine is dependent on the patient’s age\textsuperscript{154} and the presence of associated disorders, as well as the severity and duration of hypothyroidism.\textsuperscript{155} Most patients will require approximately 1.7 mcg/kg/day once they reach steady state for full replacement. Dose requirement may be better estimated based on ideal body weight, rather than actual body weight.\textsuperscript{156} In young patients with long-standing disease and patients over age 45 without known cardiac disease, therapy should be initiated with 50 mcg daily of levothyroxine and increased to 100 mcg daily after 1 month. The recommended initial daily dose for older patients or those with known cardiac disease is 25 mcg per day titrated upward in increments of 25 mcg at monthly intervals to prevent stress on the cardiovascular system. Some patients may experience an exacerbation of angina with higher doses of thyroid hormone. Although the TSH is an indicator of under- or overreplacement, clinicians often fail to alter the dose of \( T_4 \) based on TSH clearly outside of the normal range.\textsuperscript{157,158}

Patients with subclinical or mild hypothyroidism (seen more commonly for the elderly and women) have no or few signs
CHAPTER 84

Thyroid Disorders

or symptoms, normal serum T₃ and T₄ concentrations, and an elevated basal TSH concentration.¹⁹,²⁰ The prevalence of this disorder in the Third National Health and Nutrition Examination Survey (NHANES III) study was found to be 4.3%.²¹ Although the treatment of subclinical hypothyroidism is controversial, patients presenting with marked elevations in TSH (>10 milli-international units/L) and high titer of thyroid peroxidase antibody (TPOAb) or prior treatment with I¹³¹I may be most likely to benefit from treatment. Other patients who may improve with replacement include those with mild symptoms of hypothyroidism and depression. It should be noted that some studies find that only 1 of 4 treated patients experienced improvement.²⁴ Conservative treatment goals in this situation would be to maintain serum T₃ and T₄ levels in the normal range and reduce TSH to a value of 1 milli-international unit/L.

Once euthyroidism is attained, the daily maintenance dose of levothyroxine does not fluctuate greatly. As patients age, the dosing requirement may be reduced.²² Third generation TSH assays improved the accuracy with which thyroid hormone replacement can be monitored. The TSH concentration is the most sensitive and specific monitoring parameter for adjustment of levothyroxine dose. Plasma TSH concentrations begin to fall within hours and are usually normalized within 2 weeks, but they may take up to 6 weeks for some patients, depending on the baseline value. TSH and T₄ concentrations are both used to monitor therapy, and they should be checked every 6 weeks until a euthyroid state is achieved. Laboratory assessment of thyroid function should be performed approximately 6 weeks after levothyroxine dose initiation or change. This time frame allows achievement of steady state, as the half-life of levothyroxine is approximately 1 week. Serum T₃ concentrations can be useful in detecting noncompliance, malabsorption, or changes in levothyroxine product bioequivalence. An elevated TSH concentration indicates insufficient replacement. The appropriate dose maintains the TSH concentration in the normal range. Thyroxine disposal is accelerated by nephritic syndrome, other severe systemic illnesses, and several antiseizure medications (phenobarbital, phenytoin, and carbamazepine) and rifampin. Pregnancy increases the thyroxine dose requirement for 75% of women, probably because of factors such as increased degradation by the placental deiodinase, increased T₄ pool size, and transfer of T₄ to the fetus. The etiology of hypothyroidism also affects the magnitude of the dosage increase.²³ Initiating postmenopausal hormone replacement therapy increases the dose needed in 35% of women, perhaps due to an increased circulating TBG level. Patient noncompliance with prescribed thyroxine, the most common cause of inadequate treatment, might be suspected for patients with a dose that is higher than expected, variable thyroid function test results that do not correlate well with prescribed doses, and an elevated serum thyrotropin concentration with serum free thyroxine at the upper end of the normal range, which can suggest improved compliance immediately before testing due to a lag in the thyrotropin response. The metabolism of other pharmacologic agents can be altered for patients with hypothyroidism. The mechanism might be decreased expression of hepatic enzymes involved in drug metabolism, as seen in hypothyroid rats. As a result, increased sensitivity to anesthetic and sedative agents, and higher serum levels of phenytoin have been reported. Hypothyroidism can also cause higher serum digoxin values, an effect attributed to a decreased volume of drug distribution. Conversely, hypothyroidism might decrease sensitivity to warfarin due to slowed metabolism of the vitamin K-dependent clotting factors, and restoration of euthyroidism can then increase the warfarin dose requirement.

For patients with central hypothyroidism caused by hypothalamic or pituitary failure, the serum TSH cannot be used to assess adequacy of replacement. Alleviation of the clinical syndrome and restoration of serum T₄ to the normal range are the only criteria available for estimating the appropriate replacement dose of levothyroxine. Concurrent use of dopamine, dopaminergic agents (bromocriptine), somatostatin or somatostatin analogs (octreotide), and corticosteroids suppresses TSH concentrations in individuals with primary hypothyroidism and may confound the interpretation of this monitoring parameter.²³

TSH-suppressive levothyroxine therapy can be given to patients with nodular thyroid disease and diffuse goiter, to patients with a history of thyroid irradiation, and to patients with thyroid cancer. The rationale for suppression therapy is to reduce TSH secretion, which promotes growth and function in abnormal thyroid tissue. However, such management, other than for patients with thyroid cancer or with elevated TSH levels, is quite controversial. Some clinicians rarely recommend or use such therapy; others will recommend a trial of levothyroxine as suppressive therapy in some patients. The conclusions of three metaanalyses were that suppressive therapy for nodules was associated with a small decrease in nodule growth,²⁴ a statistically nonsignificant reduction in nodule growth,²⁵ and a significant reduction in nodule growth that was reduced with longer term treatment.²⁶ If suppressive therapy with levothyroxine is pursued, the age, gender, and menopausal status of the patient need to be considered, along with the risk of cardiac arrhythmias and reduced bone mineral density. Levothyroxine may be given in non toxic MNG to suppress the TSH to low-normal levels of 0.5 to 1 milli-international unit/L if the baseline TSH is >1 milli-international unit/L. Goiter size and thyroid volume may be reduced with suppression therapy. Diffuse goiter associated with autoimmune thyroiditis may also be treated with levothyroxine to reduce goiter size and thyroid volume. Levothyroxine suppression therapy is of benefit to all but the lowest risk thyroid cancer patients and is generally used in the management of patients with differentiated thyroid cancer, with the TSH goal being influenced by the patient’s thyroid cancer stage and other risk factors.²⁷ Current guidelines from the American Thyroid Association suggest suppressing the TSH to below 0.1 milli-international unit/L in higher risk patients, keeping TSH around the lower limit of normal (0.1 to 0.5 milli-international units/L) in low-risk patients.²⁸

**Adverse Effects** Serious untoward effects are unusual if dosing is appropriate and the patient is carefully monitored during initial treatment. A cross-sectional study showed that of a population of 1,525 individuals taking levothyroxine, 40% actually had abnormal TSH values.²⁹ A recent study showed that 57% of individuals 65 years or older receiving thyroid hormone treatment had abnormal TSH values.³⁰ Both of these studies suggest failure to keep a patient’s TSH at goal is common. Levothyroxine replacement in athyreotic hypothyroid patients restores systolic and diastolic left ventricular performance within 2 weeks, and the use of levothyroxine may increase the frequency of atrial premature beats but not necessarily ventricular premature beats. Excessive doses of thyroid hormone may lead to heart failure, angina pectoris, and myocardial infarction; rarely, the latter may be caused by coronary artery spasm. Allergic or idiosyncratic reactions can occur with the natural animal-derived products such as desiccated thyroid and TG, but these are extremely rare with the synthetic products used today. The 0.05 mg (50 mcg) Synthroid tablet is the least allergenic (due to a lack of dye and few excipients) and should be tried for the patient suspected to be allergic to thyroid hormone.

Hyperremodeling of cortical and trabecular bone due to hyperthyroidism leads to reduced bone density and may increase the risk of fracture. Compared with normal controls, excess exogenous thyroid hormone results in histomorphometric and biochemical changes similar to those observed in osteoporosis and untreated hyperthyroidism; however, at routinely used replacement doses,
bone mineral density loss is less than that seen with untreated hyperthyroidism and only slightly greater than in controls.170,171 The risk for this complication of therapy seems to be related to the dose of levothyroxine, patient age, and gender. Markers for bone turnover include urinary cross-linked N-telopeptides, pyridinoline of type I collagen, osteocalcin, and bone-specific alkaline phosphatase. When doses of levothyroxine are used to suppress TSH concentrations to below-normal values (less than 0.3 milli-international unit/L) in postmenopausal women, this adverse effect is more likely to be seen. Cortical bone is affected to a greater degree than trabecular bone at suppressive doses of levothyroxine. In contrast, it appears to be much less likely in men and in premenopausal women. Maintaining the TSH between 0.7 and 1.5 milli-international units/L does not alter bone mineral density in premenopausal women.

**EVALUATION OF THERAPEUTIC OUTCOMES**

**HYPOTHYROIDISM**

Patients on optimal thyroid hormone replacement therapy should have TSH and free T4 serum concentrations in the normal range. Those who are being treated for thyroid cancer should have TSH suppressed to low levels based on their risk stratification167 and their TG should be undetectable. Given the half-life of 7 days of T4, the appropriate monitoring interval is no more than 4 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see Clinical Presentation of Hypothyroidism above), although this may take several months for most to improve.

**SPECIAL CONDITIONS**

**Myxedema Coma**

Myxedema coma is a rare consequence of decompensated hypothyroidism.172,173 Clinical features include hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy. Traditionally, the initial treatment has been intravenous bolus levothyroxine 300 to 500 mcg. However, as deiodinase activity is markedly reduced, impairing T3 to T4 conversion, initial treatment with intravenous triiodothyronine or a combination of both hormones has also been advocated.173 Glucocorticoid therapy with intravenous hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out. Consciousness, lowered TSH concentrations, and normal vital signs are expected within 24 hours. Maintenance doses of levothyroxine are typically 75 to 100 mcg given intravenously until the patient stabilizes and oral therapy is begun. Supportive therapy must be instituted to maintain adequate ventilation, euglycemia, blood pressure, and body temperature. Any underlying disorder, such as sepsis or myocardial infarction, obviously must be diagnosed and treated.

**Congenital Hypothyroidism**174

In congenital hypothyroidism, full maintenance therapy should be instituted early to improve the prognosis for mental and physical development.175 The average maintenance dose in infants and children depends on the age and weight of the child. Several studies demonstrate that aggressive therapy with levothyroxine is important for normal development, and current recommendations are for initiation of therapy within 45 days of birth at a dose of 10 to 15 mcg/kg/day.124 This dose is used to keep T4 concentrations at about 10 mcg/dL within 30 days of starting therapy and is associated with improved IQs in treated infants. The dose is progressively decreased to a typical adult dose as the child ages, the adult dose being given in the age range of 11 to 20 years.

**Hypothyroidism in Pregnancy**99

Hypothyroidism during pregnancy leads to an increased rate of stillbirths and possibly lower psychological scores in infants born of women who received inadequate replacement during pregnancy.176 Thyroid hormone is necessary for fetal growth and must come from the maternal side during the first 2 months of gestation. Although iodothyronine may cross the placental membrane slightly better than levothyroxine, the latter is considered the drug of choice. The objective of treatment is to decrease TSH to 1 unit/mL and maintain free T4 concentrations in the normal range. Based on elevated TSH levels during pregnancy, it was found that the mean dose of levothyroxine had to be increased by 36 mcg/day to suppress TSH into the normal range. Increased production of binding proteins, a marginal decrease in free hormone concentration, modification of peripheral thyroid hormone metabolism, and increased thyroxine metabolism by the fetal–placental unit also contributes to increased thyroid hormone demand and the need for increased doses after delivery.100 Up to 60% of women need to have levothyroxine dose adjustment during pregnancy. Upward adjustment will be needed by the 8th week of pregnancy. The etiology of the hypothyroidism affects the magnitude of the required increase in levothyroxine dose.162 After delivery the levothyroxine dose can be reduced based on T4 concentrations and measurement of TSH, typically about 6 to 8 weeks after delivery.99 Many patients can return to their prepregnancy dose requirement.

**Effects of Hypothyroidism on Selected Medications**

Hypothyroidism may affect the metabolism and clinical efficacy of several medications. Digitalis preparations have a decreased volume of distribution in the hypothyroid state, resulting in increased sensitivity to the digitalis effect. Therefore, many hypothyroid patients achieve a therapeutic effect at lower digitalis doses. Insulin degradation may be delayed in hypothyroidism, thereby requiring a lower insulin dose. Hypothyroidism delays the catabolism of clotting factors, and if a patient stabilized on warfarin is made euthyroid with levothyroxine, the patient may become excessively anticoagulated. Respiratory depressants such as barbiturates, phenothiazines, and opioid analgesics should be avoided, because increased sensitivity may increase carbon dioxide retention and precipitate myxedema coma.

**RECOMBINANT TSH IN THYROID CANCER**

Patients with previously treated differentiated (papillary, follicular, or their respective variants) thyroid carcinoma require lifelong monitoring for recurrent disease.172,178 Two diagnostic tests that play a central role in the follow-up of these patients—serum TG measurement and radiiodine whole body scanning—are most accurate during TSH stimulation. Temporary discontinuation of thyroid hormone therapy was previously the sole effective approach for TSH-stimulated testing. However, hormone withdrawal is associated with the morbidity of hypothyroidism and occasional tumor progression. The introduction of recombinant TSH (rTSH)-stimulated testing offers an alternative therapy. Recent clinical trials have shown that the sensitivity of combined rTSH-stimulated radiiodine scanning and serum TG measurement has nearly equivalent sensitivity to testing after thyroid hormone withdrawal.127,179 Furthermore, measurement of the rTSH-stimulated TG concentration is a more sensitive way to detect residual thyroid cancer or normal tissue than TG measurement on thyroid hormone
 therapy. Postthyroidectomy adjuvant radioiodine therapy can also be administered following rTSH, instead of thyroid hormone withdrawal, with equivalent rates of remnant ablation. Patients for whom thyroid hormone withdrawal would be contraindicated may also be successfully treated with radioiodine following rTSH. A recent study reporting short-term follow-up of 3.7 years on patients receiving their remnant ablation with rTSH showed that rates of residual and recurrent thyroid cancer did not differ between patients prepared for receiving radioiodine using rTSH versus withdrawal from levothyroxine. Recently rTSH has also been used successfully to aid in the treatment of large, compressive goiters in individuals who are not surgical candidates. Radioiodine treatment, delivered following small doses of rTSH, can lead to improved radioiodine uptake and reduced goiter volume, although this is not yet an approved use of rTSH.

**NONTHYROIDAL ILLNESS**

A wide variety of abnormalities of hypothalamic–pituitary–thyroid function, serum thyroid hormone binding, and extrathyroidal thyroid hormone metabolism occurs in patients with nonthyroidal illness. These abnormalities frequently result in decreased serum T4 concentrations and, with more severe nonthyroidal disease, lead to a decreased serum free T4 concentration as well. Serum TSH concentrations are initially within the normal range but then tend to decrease with increasing severity of illness. The presence of coexisting primary hypothyroidism can be recognized for patients who have other illnesses by an elevation in the TSH concentration.

The degree and extent of the abnormality in thyroid function generally correlates with the severity of the nonthyroidal illness. These conditions are frequently referred to as the euthyroid sick syndrome. However, it is likely that these changes represent adaptive forms of hypothyroidism that serve to reduce the availability of thyroid hormones to lessen the catabolic impact of the nonthyroidal illness.

Decreased serum T3 concentrations occur in patients with both acute and chronic illnesses. The fundamental cause of decreased serum T3 concentrations in these situations is decreased extrathyroidal conversion of T4 to T3, normally mediated by T4-5′-deiodinase. A circulating inhibitor of this enzyme, perhaps interleukin-6, is present in patients with nonthyroidal illness. Serum total and free T3 concentrations are usually normal in mild illness. The serum reverse T3 concentration is characteristically high because the same enzyme, 5′-deiodinase, that is necessary to convert T3 to T2 is necessary to convert reverse T3 to its breakdown products.

Low serum T3 is seen in most critically ill patients. This change is caused by diminished serum T3 synthesis as well as impaired binding to serum transport proteins, resulting either from decreased serum concentrations of thyroid-binding globulin, thyroid-binding prealbumin, or albumin, or from inhibitors of T3 binding. The free T3 concentration is generally normal early in critical illness but also declines with more severe disease. This more severe degree of hypothyroidism, which occurs in severely ill patients, produces a greater reduction in thyroid hormone availability. The low serum T3 concentrations for patients with nonthyroidal illness indicate a grave prognosis. In two studies, more than 60% of hospitalized patients with a low serum free T3 index died. Although controversial, T3 or T4 supplementation has been of no benefit in this situation.

To confuse matters, some patients with nonthyroidal illness have elevation of their serum T4 concentration. Most commonly, this is seen in patients with psychiatric disorders during acute psychotic breaks. Thyroid hormone levels return to normal within 2 weeks after successful treatment of the underlying psychiatric disease. The occurrence of these abnormalities requires that care be taken in diagnosing hypothyroidism or hyperthyroidism for patients who have nonthyroidal illnesses.

**GOITROUS THYROID DISEASE**

Endemic goiter is the major thyroid disease throughout the world, affecting more than 200 million people. Many goitrous glands contain one or more nodules. The introduction of iodide supplementation has eliminated goiter as a major medical problem in developed countries, though it continues to be a problem in developing countries whose geographic position makes them more susceptible to iodide deficiency. In 1924, Marine postulated that periods of iodide deficiency resulted in cyclic hyperplasia and involution of thyroid follicular cells with eventual development of nodular hyperplasia. This hypothesis is still used to explain goiter formation today. Whatever the specific cause, the final common pathway appears to result from an inadequate thyroid hormone secretion with compensatory TSH secretion and eventual thyroid gland enlargement. The essential factor for the conversion of a hyperplastic iodine-deficiency goiter into a colloid goiter appears to be an acute reduction of TSH stimulation; therefore, any situation that would result in a cyclical increase and decrease in TSH secretion might eventually result in the production of a nodular goiter.

There has been an interest in the possibility that growth factors other than TSH play a role in the development of a goiter. Immunoglobulin fractions capable of stimulating thyroid growth have been found in patients with nontoxic goiter and Graves’s disease. In these patients, thyroid growth–promoting immunoglobulin titers correlate with goiter size rather than with the thyroid hormone concentration.

**PHARMACOECONOMIC CONSIDERATIONS**

Although the initial expense of surgery would seem to make it the most expensive treatment option for hyperthyroidism, the relapse rates for thionamides and RAI are higher, and in longer-term follow-up there is not much difference between treatment options nor patients’ opinions concerning treatment preferences as suggested by a 1998 study. The cost proportion between the medical and surgical treatment in younger patients is 1:2.5 (1 = U.S.$1,126) before and 1:1.3 (1 = U.S.$2,384) after inclusion of the relapse costs. The proportion between the medical, surgical, and I131 treatment in older patients is 1:2.5:1.6 (1 = U.S.$1,164) before and 1:1.6:1.4 (1 = U.S.$1,972) after inclusion of the relapse costs.

Multiple studies have addressed the role of thyroid supplementation in critically ill patients with cardiac disease, sepsis, pulmonary disease (e.g., acute respiratory distress syndrome), or severe infection, or with burn and trauma patients. In spite of a very large number of published studies, it is very difficult to form clear recommendations for treatment with thyroid hormone in the intensive care unit.
**CLINICAL CONTROVERSIES**

Although the current FDA standards of bioavailability for thyroxine products suggest that several products are bioequivalent, the relationship between $T_4$ serum concentration and TSH response suggests that the products are not truly bioequivalent. New standards of bioequivalency may need to be developed for drug products like thyroxine.

Combination therapy of $T_4 + T_3$ for hypothyroidism generally offers no objective advantage over monotherapy, although subjective patient improvement or patient preference for combination therapy has been reported in a minority of studies. However, recent data suggest that patients with certain deiodinase polymorphisms may, in fact, derive a psychological benefit from combination therapy.

Multiple studies have addressed the role of thyroid supplementation for critically ill patients with cardiac disease, sepsis, pulmonary disease (e.g., acute respiratory distress syndrome), or severe infection or for patients with burn and trauma. In spite of a very large number of published studies, it is very difficult to form clear recommendations for treatment with thyroid hormone in the intensive care unit.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Patients with idiopathic hypothyroidism and Hashimoto’s thyroiditis on optimal thyroid hormone replacement therapy should have TSH and free $T_4$ serum concentrations in the normal range. Those on optimal thyroid hormone replacement therapy should have patients with idiopathic hypothyroidism and Hashimoto’s thyroiditis and TG should be undetectable. Given the half-life of $T_4$ of 7 days, determined based on the patient’s risk of recurrence or progression, pressed to low levels, with the appropriate TSH concentration being those who are being treated for thyroid cancer should have TSH sup-

KEY CONCEPTS

1. Glucocorticoid secretion from the adrenal cortex is stimulated by adrenocorticotropic hormone (ACTH) or corticotropin that is released from the anterior pituitary in response to the hypothalamic-mediated release of corticotropin-releasing hormone (CRH).

2. To ensure the proper treatment of Cushing’s syndrome, diagnostic procedures should (1) establish the presence of hypercortisolism and (2) discover the underlying etiology of the disease.

3. The rationale for treating Cushing’s syndrome is to reduce the morbidity and mortality resulting from disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities.

4. The treatment of choice for both ACTH-dependent and ACTH-independent Cushing’s syndrome is surgery, whereas pharmacologic agents are reserved for adjunctive therapy, refractory cases, or inoperable disease.

5. Pharmacologic agents that may be used to manage the patient with Cushing’s syndrome include steroidogenesis inhibitors, adrenolytic agents, neuromodulators of ACTH release, and glucocorticoid-receptor blocking agents.

6. Spironolactone, a competitive aldosterone receptor antagonist, is the drug of choice in bilateral adrenal hyperplasia (BAH)-dependent hyperaldosteronism.

7. Addison’s disease (primary adrenal insufficiency) is a deficiency in cortisol, aldosterone, and various androgens resulting from the loss of function of all regions of the adrenal cortex.

8. Secondary adrenal insufficiency usually results from exogenous steroid use, leading to hypothalamic-pituitary-adrenal (HPA)-axis suppression followed by a decrease in ACTH release, and low levels of androgens and cortisol.

9. Virilism results from the excessive secretion of androgens from the adrenal gland and often manifests as hirsutism in females.

The adrenal glands were first characterized by Eustachius in 1563. After Addison identified a case of adrenal insufficiency in humans, adrenal anatomy and physiology flourished. Most of the work done in the early and mid-1900s centered on the glucocorticoid cortisol. With the discovery of aldosterone by Simpson and Tait in 1952, adrenal pharmacology turned toward the mineralocorticoid. Conn followed with his classical description of primary aldosteronism in 1955, and numerous clinicians and investigators have continued to explore the variety of disease processes promoted through the adrenal gland.

The adrenal glands are located extraperitoneally to the upper poles of each kidney (Fig. 85–1). On average, each adrenal gland weighs 4 g and is 2 to 3 cm in width and 4 to 6 cm in length. The gland is fed by small arteries from the abdominal aorta and renal and phrenic arteries. Drainage of the adrenal gland occurs via the renal vein on the left and the inferior vena cava on the right.

The adrenal medulla occupies 10% of the total gland and is responsible for the secretion of catecholamines. The adrenal cortex accounts for the remaining 90% and is responsible for the secretion of three types of hormones (Fig. 85–2) from three separate zones.

The zona glomerulosa accounts for 15% of the total adrenal cortex and is responsible for mineralocorticoid production, of which aldosterone is the principal end product. Aldosterone maintains electrolyte and volume homeostasis by altering potassium and magnesium secretion and renal tubular sodium reabsorption. The zona fasciculata, the middle zone, makes up 60% of the cortex,
Endocrinologic Disorders

SECTION 8

Adrenal steroid hormone synthesis begins with the conversion of cholesterol to pregnenolone by cytochrome P450 (CYP) enzymatic side-chain cleavage. Following this rate-limiting step, pregnenolone is converted to various 19- and 21-carbon steroids, depending on the enzymatic capabilities within each zone of the cortex. Androgenic properties predominate in the 19-carbon steroids, whereas mineralocorticoid and glucocorticoid properties manifest in the 21-carbon steroids.

Aldosterone production is initiated by the 21-hydroxylation of progesterone to form deoxycorticosterone. Subsequently, aldosterone synthase converts deoxycorticosterone to aldosterone through the intermediary, corticosterone. The zona glomerulosa preferentially produces aldosterone for three main reasons. First, the zona glomerulosa lacks 17α-hydroxylase activity and therefore can only convert pregnenolone to progesterone. Secondly, in contrast to the other zones, cells in the zona glomerulosa possess aldosterone synthase activity, which catalyzes the terminal steps in aldosterone synthesis. Lastly, cells of the zona glomerulosa display a greater number of angiotensin II receptors than cells of the other zones. Binding of angiotensin II to these receptors provides the stimulus for initiating the aldosterone biosynthesis cascade. Thus, aldosterone synthesis is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the fasciculata and/or reticularis.

Cortisol is produced from pregnenolone via four successive hydroxylations. These hydroxylations occur primarily in the zona fasciculata although the zona reticularis is also capable of producing glucocorticoids.

Androgens, produced primarily in the zona reticularis and less commonly in the zona fasciculata, have a 19-carbon structure and serve as precursors to more potent analogs produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, these synthesized quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 85–1.

Glucocorticoid metabolism occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as modifying active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for conversion to the active prednisolone and cortisol, respectively.

Following metabolic conversion, glomerular filtration is primarily responsible for eliminating endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes, whereas aldosterone exhibits extremely high intrinsic clearance and a corresponding half-life of only 15 minutes.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs known to enhance steroid clearance include phenytoin, phenobarbital, rifampin, mitotane, and aminoglutethimide. Likewise, diseases is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and influence the reproductive system in addition to modulating primary and secondary sex characteristics.

HORMONE PRODUCTION AND METABOLISM

Adrenal steroid hormone synthesis begins with the conversion of cholesterol to pregnenolone by cytochrome P450 (CYP) enzymatic side-chain cleavage. Following this rate-limiting step, pregnenolone is converted to various 19- and 21-carbon steroids, depending on the enzymatic capabilities within each zone of the cortex. Androgenic properties predominate in the 19-carbon steroids, whereas mineralocorticoid and glucocorticoid properties manifest in the 21-carbon steroids.

Aldosterone production is initiated by the 21-hydroxylation of progesterone to form deoxycorticosterone. Subsequently, aldosterone synthase converts deoxycorticosterone to aldosterone through the intermediary, corticosterone. The zona glomerulosa preferentially produces aldosterone for three main reasons. First, the zona glomerulosa lacks 17α-hydroxylase activity and therefore can only convert pregnenolone to progesterone. Secondly, in contrast to the other zones, cells in the zona glomerulosa possess aldosterone synthase activity, which catalyzes the terminal steps in aldosterone synthesis. Lastly, cells of the zona glomerulosa display a greater number of angiotensin II receptors than cells of the other zones. Binding of angiotensin II to these receptors provides the stimulus for initiating the aldosterone biosynthesis cascade. Thus, aldosterone synthesis is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the fasciculata and/or reticularis.

Cortisol is produced from pregnenolone via four successive hydroxylations. These hydroxylations occur primarily in the zona fasciculata although the zona reticularis is also capable of producing glucocorticoids.

Androgens, produced primarily in the zona reticularis and less commonly in the zona fasciculata, have a 19-carbon structure and serve as precursors to more potent analogs produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, these synthesized quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 85–1.

Glucocorticoid metabolism occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as modifying active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for conversion to the active prednisolone and cortisol, respectively.

Following metabolic conversion, glomerular filtration is primarily responsible for eliminating endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes, whereas aldosterone exhibits extremely high intrinsic clearance and a corresponding half-life of only 15 minutes.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs known to enhance steroid clearance include phenytoin, phenobarbital, rifampin, mitotane, and aminoglutethimide. Likewise, diseases is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and influence the reproductive system in addition to modulating primary and secondary sex characteristics.

HORMONE PRODUCTION AND METABOLISM

Adrenal steroid hormone synthesis begins with the conversion of cholesterol to pregnenolone by cytochrome P450 (CYP) enzymatic side-chain cleavage. Following this rate-limiting step, pregnenolone is converted to various 19- and 21-carbon steroids, depending on the enzymatic capabilities within each zone of the cortex. Androgenic properties predominate in the 19-carbon steroids, whereas mineralocorticoid and glucocorticoid properties manifest in the 21-carbon steroids.

Aldosterone production is initiated by the 21-hydroxylation of progesterone to form deoxycorticosterone. Subsequently, aldosterone synthase converts deoxycorticosterone to aldosterone through the intermediary, corticosterone. The zona glomerulosa preferentially produces aldosterone for three main reasons. First, the zona glomerulosa lacks 17α-hydroxylase activity and therefore can only convert pregnenolone to progesterone. Secondly, in contrast to the other zones, cells in the zona glomerulosa possess aldosterone synthase activity, which catalyzes the terminal steps in aldosterone synthesis. Lastly, cells of the zona glomerulosa display a greater number of angiotensin II receptors than cells of the other zones. Binding of angiotensin II to these receptors provides the stimulus for initiating the aldosterone biosynthesis cascade. Thus, aldosterone synthesis is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the fasciculata and/or reticularis.

Cortisol is produced from pregnenolone via four successive hydroxylations. These hydroxylations occur primarily in the zona fasciculata although the zona reticularis is also capable of producing glucocorticoids.

Androgens, produced primarily in the zona reticularis and less commonly in the zona fasciculata, have a 19-carbon structure and serve as precursors to more potent analogs produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, these synthesized quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 85–1.

Glucocorticoid metabolism occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as modifying active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for conversion to the active prednisolone and cortisol, respectively.

Following metabolic conversion, glomerular filtration is primarily responsible for eliminating endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes, whereas aldosterone exhibits extremely high intrinsic clearance and a corresponding half-life of only 15 minutes.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs known to enhance steroid clearance include phenytoin, phenobarbital, rifampin, mitotane, and aminoglutethimide. Likewise, diseases is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and influence the reproductive system in addition to modulating primary and secondary sex characteristics.
such as hyperthyroidism and renal disease (dexamethasone only) can enhance steroid clearance. In contrast, drugs such as estrogens and estrogen-containing oral contraceptives reduce steroid clearance. Similarly, liver disease, age, pregnancy, hypothyroidism, anorexia nervosa, protein-calorie malnutrition, and renal disease (prednisolone only) are associated with reduced steroid clearance.

Plasma glucocorticoids are bound to one of three plasma proteins in varying degrees. Corticosteroid-binding globulin (CBG), albumin, and \( \alpha \)-glycoprotein are capable of binding glucocorticoids, with CBG being the principal binding protein. Steroid binding serves as a reservoir for steroids in their inactive state and ≥95% of cortisol is normally bound in this fashion. This binding prevents glucocorticoid activity at receptor-activating sites. Therefore, a final but important variable in altered plasma concentration of free (active) steroids is concentration of plasma proteins.

**REGULATION OF HORMONE SECRETION**

Glucocorticoid secretion is regulated by the pituitary hormone, ACTH (also known as corticotropin). Under normal conditions, ACTH is released from the anterior pituitary in response to CRH, which is secreted by the median eminence of the hypothalamus (Fig. 85-3). Vasopressin and oxytocin have weak ACTH-releasing activity through binding to the inferior V1 receptor. CRH, in combination with vasopressin and oxytocin, stimulates greater ACTH secretion than each hormone individually.

Additionally, histochemical studies have demonstrated that certain neurotransmitters have the unique ability to stimulate production of CRH or ACTH directly. Specifically, 5-hydroxytryptamine and norepinephrine have both been shown to increase levels of ACTH. After release, ACTH stimulates the adrenal gland to release cortisol and, to a lesser extent, aldosterone and androgens. The rising cortisol concentration inhibits the secretion of CRH and ACTH through a negative-feedback mechanism. In addition, leptin, an adipocyte hormone, can have an inhibitory effect on HPA activity.

Adrenal androgens are regulated in a similar fashion to cortisol. When plasma androgen reaches sufficient concentrations, production is terminated via a negative feedback loop. Androgen release is increased during puberty and in women with hirsutism. Adrenal androgen release decreases with age and in fasting states, including anorexia nervosa.

In contrast to cortisol and adrenal androgens, regulation of aldosterone secretion is considerably more complex. The renin-angiotensin system regulates aldosterone secretion through both intrarenal and extrarenal mechanisms. Renin production and subsequent aldosterone secretion is stimulated by blood pressure lowering (due to volume depletion), erect posture, salt depletion, \( \beta \)-adrenergic stimulation, and central nervous system excitation (see Chap. 15). Renin production is inhibited by salt loading, angiotensin II, vasopressin, potassium, calcium, blood pressure increases, and a variety of drugs. The renin-mediated production of angiotensin II is the initial stimulus for aldosterone synthesis. Additionally, angiotensin II can be acted on by aminopeptidase and converted to angiotensin III. Angiotensin II and III are both capable of stimulating the zona glomerulosa to secrete aldosterone.

Following aldosterone secretion, increases in renal sodium and water retention as well as blood pressure occur, thereby turning off the stimulus for renin release.

**HYPERFUNCTION OF THE ADRENAL GLAND**

**CUSHING’S SYNDROME**

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. Until this time, no definitive diagnosis existed for patients with unexplained central obesity, cutaneous striae, osteoporosis, weakness, hypertension, diabetes mellitus, and congestion. Cushing emphasized that the disease was of a pituitary origin. Ten years later, Albright focused his attention on the sugar hormone, which he believed originated from the adrenal cortex.1

After the development of a method for measuring urinary steroids, Daughaday discovered elevated steroids in the urine of patients with Cushing’s syndrome. Finally, the end product was identified, and Cushing’s syndrome was correctly explained as an excess of cortisol in the plasma (hypercortisolism).

**Etiology**

Cushing’s syndrome results from the effects of supraphysiologic levels of glucocorticoids originating either from exogenous administration or less commonly, from endogenous overproduction by the adrenal glands. Excess glucocorticoids are produced in response to overproduction of ACTH (ACTH-dependent) or by abnormal adrenocortical tissues regardless of ACTH stimulation (ACTH-independent). ACTH-dependent Cushing’s syndrome (≈80% of all Cushing’s cases) usually originates from overproduction of ACTH by the pituitary gland, which chronically stimulates the adrenal glands causing bilateral adrenal hyperplasia. Approximately 85% of these cases are caused by pituitary adenomas (Cushing’s disease). Ectopic ACTH-secreting tumors and non-neoplastic corticotropin hypersecretion, possibly secondary to excess CRH production, account for the remainder of ACTH-dependent causes.2 Ectopic ACTH syndrome refers to excessive ACTH production resulting from an endocrine or nonendocrine tumor, usually of the pancreas, thyroid, or lung. Small-cell carcinoma of the lung will lead to ectopic ACTH secretion in 0.5% to 2% of cases, whereas bronchial carcinoid tumors are usually the most common.3 Distinguishing

between the various etiologies requires a careful history and pertinent laboratory work (Table 85–2).

The remaining 20% of Cushing’s syndrome cases are ACTH-independent and divided almost equally between adrenal adenomas and adrenal carcinomas, with rare cases caused by macronodular hyperplasia, primary pigmented nodular adrenal disease, and McCune-Albright syndrome. The majority of adrenal cortex tumors are benign adenomas. Adrenal carcinoma is found more often in children than in adults with Cushing’s syndrome.

Clinical Presentation

Patients with Cushing’s syndrome commonly present (>90% of patients) with central obesity and facial rounding. In addition, approximately 50% of patients will exhibit some peripheral obesity and fat accumulation. Fat accumulation in the dorsocervical area (buffalo hump) can be associated with any major weight gain, whereas increased supracavicular fat pads are more specific for Cushing’s syndrome. Striae usually are present along the lower abdomen and take on a red to purple color. Traditionally, hypertensive complications have been major contributors to the morbidity and mortality of Cushing’s syndrome. Hypertension is diagnosed in 75% to 85% of patients, with diastolic blood pressures greater than 119 mm Hg noted in over 20% of patients. In addition, glucose intolerance is present in 60% of patients. Thus, many patients meet diagnostic criteria for the metabolic syndrome and have a corresponding increased risk of CHD and stroke. Screening for Cushing’s syndrome in this population and in patients with uncontrolled diabetes mellitus has been suggested, particularly when these conditions surface at an unusually early age.

CLINICAL CONTROVERSY

Traditionally, obesity was used as screening tool because of its high prevalence in Cushing’s syndrome. However, given the current epidemic of obesity, routine screening in all overweight and obese individuals may result in a high rate of false-positive tests.

Diagnosis

The diagnosis of Cushing’s syndrome involves two steps: (1) establishing the presence of hypercortisolism, which is relatively easy; and (2) differentiating between etiologies, which can be challenging (Fig. 85–4). The presence of hypercortisolism can be established via the following tests: 24-hour urinary free cortisol (UFC), midnight plasma cortisol, late-night salivary cortisol, and/or the low-dose dexamethasone suppression test (DST) (using 1 mg dexamethasone for the overnight test or 0.5 mg/6 h for the classic 2-day study). However, because these tests cannot determine the etiology of Cushing’s syndrome, other tests and procedures will be subsequently employed. Such tests can include any of the following: plasma ACTH via IRMA or RIA; adrenal vein catheterization; metyrapone stimulation test; adrenal, chest, or abdominal CT; CRH stimulation test; IPSS; JVS; cavernous sinus sampling; and pituitary MRI. High-dose DST has been used in the past, but is no longer recommended due to its poor specificity and limited diagnostic value. Other possible tests and procedures include insulin-induced hypoglycemia, somatostatin receptor scintigraphy, the desmopressin stimulation test, the naloxone CRH stimulation test, the loperamide test, the hexarelin stimulation test, and radionuclide imaging. Table 85–3 summarizes some of the tests used to diagnose Cushing’s syndrome.

Elevated UFC concentrations are highly suggestive of Cushing’s syndrome, especially values fourfold greater than the upper limit of normal. In contrast to plasma measurements of cortisol, UFC measures only unbound cortisol. Consequently, the UFC test is unaffected by conditions and medications that alter CBG levels. Normal reference values for UFC are 20 to 90 mcg per 24-hour period. A two- to threefold increase in urine cortisol is not uncommon in the patient with hyperfunction of the adrenal gland. Starvation, hydration from water loading (greater than 5 liters per day), alcoholism, and acute stress are all capable of elevating urine cortisol concentrations. Likewise, elevated UFC results can occur during therapy with topical steroids, carbamazepine, and fenofibrate depending on the type of UFC test. Conversely, renal impairment (CrCl of less than 60 mL/min) can falsely lower UFC concentrations. Because other pathologic conditions can increase the amount of free cortisol, additional tests may be warranted to confirm the diagnosis, or the diagnostic evaluation should be repeated when the acute stress has resolved. Of all urinary measures, UFC is the most useful assessment for patients with suspected Cushing’s syndrome.

Gradient on IPSS or JVS

No gradient on IPSS or JVS

Cushing’s Disease

Ectopic ACTH syndrome

Psychiatric changes can occur in as many as 55% of patients.
Approximately 50% to 60% of patients will develop Cushing-induced osteoporosis. Of these, 40% will present with back pain and 20% will progress to compression fractures of the spine.
Gonadal dysfunction is common with amenorrhea seen in up to 75% of females.
Excess adrenal and ovary androgen secretion is responsible for 80% of females presenting with hirsutism.

Laboratory Tests
A midnight plasma cortisol, late-night salivary cortisol, 24-hour UFC, and/or low-dose DST will establish the presence of hypercortisolism.

Other Diagnostic Tests
The plasma ACTH test, metyrapone stimulation test, CRH stimulation test, or inferior petrosal sinus sampling will help determine the etiology.

ACTH, adrenocorticotropic hormone; DST, dexamethasone suppression test.
In healthy individuals, cortisol release follows a circadian rhythm whereby serum cortisol levels peak around 8:00 AM and thereafter decline by 60% to 80%, reaching a nadir between 3:00 and 4:00 AM. This rhythm is lost in the Cushing’s syndrome patient. Although many patients with Cushing’s syndrome will have serum cortisol values in the high normal range if the serum is assayed in the morning, only 3.4% will have normal values if measured late at night. Thus, a midnight serum cortisol greater than 7.5 mcg/dL (>1.8 mcg/dL if the patient is sleeping) is a highly sensitive assay for Cushing’s syndrome. However, this test is cumbersome and rarely recommended because it requires that patients be admitted for more than 48 hours to avoid false-positive responses secondary to the stress of hospitalization. An alternative assay is the measurement of late-night salivary cortisol. Salivary cortisol is highly correlated with free serum cortisol and independent of salivary flow rates. Moreover, salivary cortisol concentrations reflect changes in serum cortisol within minutes. Salivary cortisol can be considered as an acceptable alternative to UFC because of its convenience, stability (one week), accuracy, and reproducibility. Unfortunately, normal reference ranges are assay-dependent, and cutoff points vary among institutions.

In the overnight DST, 1 mg of dexamethasone is administered at 11:00 PM. The following morning at 8:00 AM fasting plasma cortisol is obtained for analysis. This supraphysiologic dose suppresses ACTH stimulation and cortisol production in healthy individuals. In contrast, the negative feedback loop is ineffective in patients with Cushing’s syndrome who generally exhibit morning cortisol concentrations above 5 mcg/dL. Some patients with Cushing’s syndrome administered the overnight DST can slightly suppress cortisol and using 1.8 mcg/dL as a cutoff can increase sensitivity, but at the expense of reduced specificity. Therefore, the overnight DST is useful only as a screening tool for Cushing’s syndrome. Drugs that induce or inhibit CYP3A4 metabolism can significantly alter dexamethasone levels, increasing the number of false-positive and false-negative DST tests. Concurrent measurements of dexamethasone levels with cortisol may improve the accuracy of testing for patients on CYP3A4 modifying drugs, although dexamethasone assays are not widely available. Also noteworthy, pregnancy and estrogen use (including oral contraceptives) increase CBG levels and frequently illicit false-positive results. Consequently, UFC testing is preferred over DST in these patient populations.

The first test used to determine the etiology of Cushing’s syndrome is the plasma ACTH test. Plasma ACTH concentrations can be measured via RIA or IRMA. In ACTH-dependent Cushing’s syndrome, ACTH can be normal or elevated. Very high levels of ACTH favor ectopic production. In contrast, ACTH values generally are low (less than 5 pg/mL) in ACTH-independent (adrenal) Cushing’s syndrome. Furthermore, ACTH levels can appear artificially low in some ectopic ACTH-producing tumors because ACTH can be secreted as an active prohormone that is not detected by the assay.

IPSS offers the highest sensitivity and specificity of any test in differentiating the etiology of Cushing’s syndrome. This technique requires catheterization of both petrosal sinuses with serial measurements of ACTH in each sinus and a peripheral vein after administration of CRH. A central-to-territorial ACTH gradient is diagnostic for Cushing’s disease whereas no gradient indicates ectopic ACTH production. Complications, such as venous thromboembolism, brain stem vascular damage, cost, and technical expertise can limit use of this test. JVS uses the same concept as IPSS, is less invasive, and produces fewer complications; however, sensitivity is compromised.

Abnormal adrenal anatomy is effectively identified using high-resolution CT scanning and MRI. Nodules as small as 1 to 1.5 cm on the adrenal cortex are easily identified by CT. With the use of thin-section scanning, nodules as small as 3 to 5 mm can be visualized. Importantly, adrenal incidentalomas are prevalent in 5% to 10% of the general population. These masses may be functional (secreting), requiring intervention, or nonfunctional (nonsecreting), requiring only periodic observation. For this reason, abnormal imaging results are unable to conclusively diagnose adrenal disease when used alone. Non-adrenal imaging studies may be useful for identifying ectopic sources of ACTH secretion in patients for whom IPSS has ruled out Cushing’s disease.

**Differential Diagnosis**

Iatrogenic (exogenous) Cushing’s syndrome is the most common form of the disease. Therefore, all patients exhibiting hypercortisolism should undergo a comprehensive history and evaluation assessing medication use before laboratory testing is performed to identify endogenous causes. Iatrogenic Cushing’s syndrome can occur from administration of oral, inhaled, intranasal, intraarticular, and topical glucocorticoids, as well as progestins such as medroxyprogesterone acetate and megestrol acetate. Disease severity correlates with exogenous glucocorticoid potency, dose, frequency, route, and treatment duration. Moreover, patients taking CYP3A4 inhibitors concomitantly with a glucocorticoid can be at higher risk of developing iatrogenic Cushing’s syndrome. If exogenous glucocorticoids are being taken, plasma cortisol levels can increase, while corticosterone levels remain low.

In the absence of any known exogenous causes, the clinician will need to differentiate the syndrome from other syndromes, such as Pseudo-Cushing’s syndrome, that mimic Cushing, Patients with obesity, chronic alcoholism, depression, and acute illness of any type can present with certain features of Cushing’s syndrome. However, these patients may lack true Cushing’s syndrome. For example, depressed patients, although mimicking the urinary steroid abnormalities of Cushing’s syndrome, will not resemble a cushingoid patient in appearance. In chronic alcoholics, steroid laboratory panels generally return to baseline after ceasing alcohol intake. And obese patients often will have normal cortisol concentrations on both serum and urinary screening. Thus, identifying true cases of Cushing’s syndrome requires a comprehensive history in combination with laboratory and possibly imaging assessment.

**TREATMENT**

1. If left untreated, Cushing’s syndrome is associated with high morbidity and mortality owing to associated disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities. These disorders limit the survival of the patient with Cushing’s syndrome to 4 to 5 years following initial diagnosis. The desired outcomes of treatment are to limit such detrimental outcomes and return the patient to a normal functional state by removing the source of hypercortisolism without causing any pituitary or adrenal deficiencies.

2. The treatment of choice for both ACTH-dependent and ACTH-independent Cushing’s syndrome is surgical resection of any offending tumors. However, several secondary pharmacologic treatment plans are available, depending on the etiology of the disease (Table 85–4). These pharmacologic options are generally used in preoperative patients or as adjunctive therapy in postoperative patients awaiting response. Rarely, monotherapy is used as a palliative treatment when surgery is not indicated.

**PHARMACOLOGIC THERAPY**

3. Pharmacotherapy of Cushing’s syndrome (dosing can be found in Table 85–4) can be divided into four categories based on the anatomic site of action of the agent: (1) steroidogenesis inhibitors,

ACTH, adrenocorticotropic hormone.

(2) adrenolytic agents, (3) neuromodulators of ACTH release, and (4) glucocorticoid-receptor blocking agents.  

Steroidogenesis Inhibitors

As their name implies, steroidogenesis inhibitors block the production of cortisol. This class includes metyrapone, ketoconazole, etomidate, and aminoglutethimide. Metyrapone inhibits its 11β-hydroxylase, the enzyme responsible for converting 11-deoxycortisol to cortisol. Following administration, a sudden decrease in cortisol levels occurs within hours and prompts a compensatory rise in plasma ACTH concentrations. As ACTH increases and blockage of cortisol synthesis persists, adrenal steroidogenesis efforts are shunted toward androgen production. Consequently, metyrapone is associated with significant androgenic side effects, including hirsutism and increased acne. In addition, metyrapone blocks aldosterone synthesis and causes the accumulation of aldosterone precursors, which exhibit weak mineralocorticoid activity. Blood pressure and electrolyte level variations can ensue, depending on the level of circulating 11-deoxycortisol and the degree of aldosterone inhibition. Additional adverse effects, including nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, and allergic rash, have been reported following administration, but are often signs of overtreatment.  

Metyrapone is currently available through the manufacturer only for compassionate use. The imidazole derivative antifungal, ketoconazole, effectively inhibits steroidogenesis via multiple mechanisms when used in large doses. In contrast to the quick onset of metyrapone, the benefits of ketoconazole therapy are achieved over several weeks of therapy. In addition to lowering serum cortisol levels, ketoconazole exhibits anti-androgenic activity attributable to its inhibition of multiple CYP enzymes as well as 11β-hydroxylase and 17α-hydroxylase. This activity may be beneficial in female patients with Cushing’s syndrome, but can cause gynaecomastia and decreased libido in males. Sustained therapy with ketoconazole also imparts beneficial effects on serum cholesterol profiles, including lowering total and LDL cholesterol levels. Ketoconazole induces a reversible elevation of hepatic transaminases in approximately 10% of patients. Frequent liver function monitoring is recommended although progression to serious hepatotoxicity is rare. Additional common adverse effects include gastrointestinal discomfort and dermatologic reactions.

Ketoconazole may be used concomitantly with metyrapone to achieve synergistic reductions in cortisol levels. Because these drugs differ in their onset of action, coadministration allows for more complete suppression of cortisol synthesis. Moreover, the anti-androgenic actions of ketoconazole therapy may offset the androgenic potential of metyrapone, thus attenuating a major limitation of metyrapone therapy.

The anesthetic etomidate is an imidazole derivative similar to ketoconazole that inhibits 11β-hydroxylase. Etomidate is available only in a parenteral formulation and is therefore limited to patients with acute hypercortisolism requiring emergency treatment.

Initially, aminoglutethimide was used to treat refractory forms of epilepsy, but was later discovered to be a potent inhibitor of adrenal steroid synthesis. Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone early in the steroid biosynthesis pathway, thereby inhibiting the production of cortisol, aldosterone, and androgens. Owing to these broad inhibitory actions, side effects, including severe sedation, nausea, ataxia, and skin rashes, limit the use of aminoglutethimide in many patients. Moreover, because other steroidogenesis inhibitors offer greater efficacy combined with fewer side effects, aminoglutethimide has fallen out of favor in the treatment of Cushing’s syndrome. If aminoglutethimide is used, it should be coadministered with another steroidogenesis inhibitor, usually metyrapone, secondary to high relapse rates with aminoglutethimide monotherapy.

Adrenolytic Agents

Mitotane is a cytotoxic drug that structurally resembles the insecticide dichlorodiphenyltrichloroethane (DDT). Mitotane inhibits the 11-hydroxylation of 11-deoxycortisol and 11-deoxycorticosterone in the cortex, resulting in a net inhibition of cortisol and corticosterone synthesis. Similar to ketoconazole, mitotane takes weeks to months to exert beneficial effects. Sustained cortisol suppression occurs in most patients and may persist following discontinuation of therapy in up to one third of patients. Because of its cytotoxic nature, mitotane degenerates cells within the zona fasciculata and reticularis, resulting in atrophy of the adrenal cortex. The zona glomerulosa is minimally affected during acute therapy but can become damaged following long-term treatment. Mitotane can induce significant neurological and gastrointestinal side effects and patients should be monitored carefully or hospitalized when initiating therapy. Nausea and diarrhea are common adverse effects that occur at doses greater than 2 g/day and can be avoided by gradually increasing the dose and/or administering the agent with food. Approximately 80% of patients treated with mitotane develop lethargy and somnolence, and other central nervous system adverse drug reactions occur in approximately 40% of patients. Furthermore, significant but reversible hypercholesterolemia and prolongation of bleeding times can result...
from mitotane use\textsuperscript{25,26}. Mitotane increases production of corticos-
teroid binding globulin resulting in elevated plasma cortisol; thus, UFC and urinary steroid production should be monitored to assess response to therapy.\textsuperscript{21} If necessary, steroid replacement therapy can be given. However, because mitotane also increases extraadrenal metabolism of exogenously administered corticosteroids, higher steroid replacement doses may be required.

Neuromodulatory Agents

Pituitary secretion of ACTH is normally mediated by various neurotransmitters, including serotonin, GABA, acetylcholine and the catecholamines. Although ACTH-secreting pituitary tumors (Cushing’s disease) self-regulate ACTH production to some degree, these neurotransmitters are still capable of promoting pituitary ACTH production. Consequently, agents that target these neurotransmitters have been proposed for the treatment of Cushing’s disease. Such agents include cyproheptadine, ritanserin, ketanserin, bromocriptine, cabergoline, valproic acid, octreotide, lanreotide, rosiglitazone, and tretnoin. However, none of these drugs have demonstrated consistent clinical efficacy in the treatment of Cushing’s disease.

Cyproheptadine, a nonselective serotonin receptor antagonist and anticholinergic drug, can decrease ACTH secretion in some Cushing’s disease patients. However, side effects, including sedation and weight gain, significantly limit the use of this drug. Likewise, selective serotonin type 2 receptor antagonists, including ritanserin and ketanserin, have demonstrated limited efficacy. Owing to their poor efficacy and high relapse rates, these drugs should be avoided except in nonsurgical candidates refractory to more conventional treatments.

Dopamine D\textsubscript{2} receptor agonists, including bromocriptine and cabergoline, initially reduce ACTH secretion in as many as half of all patients with Cushing’s disease. This action occurs through activation of inhibitory D\textsubscript{2} receptors that are expressed in approximately 80% of pituitary adenomas.\textsuperscript{26} Reductions in ACTH levels are often minor and rarely sustained with long-term bromocriptine therapy. Cabergoline exhibits a higher specificity and affinity for D\textsubscript{2} receptors as well as a prolonged half-life compared with bromocriptine, but long-term studies for cabergoline are lacking.

The somatostatin analogues, octreotide and lanreotide, generally are ineffective in reducing ACTH secretion in Cushing’s disease. These two agents primarily target somatostatin receptor subtype 2 (sst\textsubscript{2}), whereas pituitary adenomas predominantly express sst\textsubscript{1}. Pasireotide, an investiga-
tional somatostatin analogue, exhibits a high affinity for both sst\textsubscript{1} and sst\textsubscript{2}, and may show promise as a future treatment in Cushing’s disease.

Glucocorticoid-Receptor Blocking Agents

Mifepristone (RU-486) is a potent progesterone- and glucocorticoid-receptor antagonist that inhibits dexamethasone suppression and increases endogenous cortisol and ACTH levels in normal subjects.\textsuperscript{25,28} Limited clinical experience in Cushing’s syndrome suggests that mifepristone is highly effective in reversing the manifestation of hypercortisolism. Though because of its novel site of action, mifepristone induces a compensatory rise in ACTH and cortisol levels. Consequently, efficacy and toxicity monitoring must rely on clinical signs rather than laboratory assessments. Given these monitoring challenges, mifepristone use remains investigational for the treatment of Cushing’s syndrome.

Close monitoring of 24-hour UFC levels and serum cortisol lev-
els are essential to detect treatment-induced adrenal insufficiency. Steroid secretion should be monitored with all of these drugs and steroid replacement given as needed. Whatever the choice, pharmacologic therapy in pituitary-dependent disease is mainly centered around patient stabilization prior to surgery or in patients waiting for potential response to other therapies.

\section*{NONPHARMACOLOGIC THERAPY}

\subsection*{Surgery}

The treatment of choice for Cushing’s disease is transsphenoidal resection of the pituitary microadenoma.\textsuperscript{3,10,12} The advantages of this procedure include preservation of pituitary function, low complica-
tion rate, and high clinical improvement rate. The overall cure rate of histologically proven microadenomas approaches 90%, whereas remission rates for macroadenomas generally do not exceed 65%.

For persistent disease following transsphenoidal surgery or when tumor-specific surgery is not possible, several second-line treatment options are available and should be tailored toward the individual patient. In the case of persistent disease following transsphenoidal surgery, repeat surgery may be performed, although overall remis-
sion rates are lower with subsequent procedures. Alternatively, radio-
therapy may be preferred for tumors invading the dura or cavernous sinus because these tumors respond poorly to surgical intervention.\textsuperscript{19}

Radiotherapy provides clinical improvement in approximately 50% of patients within 3 to 5 years, but increases the risk for pituitary-
dependent hormone deficiencies (hypopituitarism).

Laparoscopic adrenalectomy is often preferred in patients with unilateral adrenal adenomas for whom transsphenoidal surgery and pituitary radiotherapy have failed or cannot be used.\textsuperscript{3,10,28} Bilateral adrenalectomy rapidly reverses hypercortisolism. However, patients can develop Nelson syndrome, an aggressive pituitary tumor that secretes high quantities of ACTH, which causes hyperpigmentation. Because Nelson syndrome occurs in as many as 30% of bilateral adrenalectomy cases, patients should undergo regular MRI scans and ACTH level assessments. Additionally, these patients require lifelong glucocorticoid and mineralocorticoid supplementation.

\subsection*{Adrenal Adenoma}

Surgical resection of benign adrenal adenoma is associated with relatively few side effects and a high cure rate (95%). The contralateral gland in the patient with adrenal adenoma is usually atrophic, therefore steroid replacement is needed both peri-
operatively and postoperatively. \textbf{Table 85–5} outlines an approach to steroid replacement for three separate routes of hydrocortisone. Therapy should be continued for 6 to 12 months following surgery. Before replacement therapy is discontinued, recovery of the adrenal axis can be assessed by measuring the morning (8 AM) cortisol level. Cortisol levels should exceed 20 mcg/dL before discontinuing exogenous steroids.\textsuperscript{22}

\textsuperscript{a}Add hydrocortisone 0.05–2 mg orally once daily starting on postoperative day 3. Adjust dose based on blood pressure, body weight, and serum electrolytes.
Adrenal Carcinoma

Unlike the benign adenoma patient, those with adrenal carcinoma have an unfavorable outcome with surgical resection. Often the complete tumor cannot be excised, leaving the patient with some degree of symptomatology and extraadrenal involvement. Radiotherapy can be used if metastases are discovered. In the patient with adrenal carcinoma who is not a surgical candidate, the focus of treatment is on palliative pharmacologic intervention.

Mitotane may be used in inoperable functional and non-functional adrenal carcinoma or as adjuvant therapy in surgical patients with a high risk of relapse. However, mitotane induces tumor regression in less than 20% of patients. Metrapone, aminoglutethimide, and ketoconazole can be given to attempt control of steroid hypersecretion. 5-fluorouracil also has been used in combination therapy.

Ectopic ACTH Syndrome

In ectopic ACTH syndrome, ACTH-secreting tumors may exist in a variety of sites, including thymic, pulmonary, appendiceal, pancreatic, and thyroid tissues. Locating these sites is often difficult, but essential for determining an appropriate treatment strategy. Surgical resection is the most effective treatment option for these patients, but only approximately 10% to 30% of patients are cured following surgery due to high rates of metastatic disease or occult tumors. The remaining 70% to 90% receive postoperative medication.

Pharmacologic management with steroidogenesis inhibitors is effective in ectopic ACTH syndrome. Mitotane has been used in patients with ectopic ACTH syndrome; however, its side-effect profile generally limits its use. Mifapristone and somatostatin analogs also have been reported to reduce the clinical signs of ectopic ACTH syndrome. Additional tumor-directed therapy can include systemic chemotherapy, interferon α, chemoembolization, radiofrequency ablation, and radiation therapy. If all else fails, bilateral adrenalectomy can prevent the downstream effects (e.g., steroidogenesis) of high levels of tumor ACTH secretion.

HYPERALDOSTERONISM

Excess aldosterone secretion is categorized as either primary or secondary hyperaldosteronism. In primary aldosteronism (PA), the stimulation for aldosterone secretion arises from within the adrenal gland. Conversely, extraadrenal stimulation is classified as secondary aldosteronism.

Primary Aldosteronism

Etiology The most common causes of PA include BAH (65%) and aldosterone-producing adenoma (APA; otherwise known as Conn syndrome) (30%). Other rare causes include unilateral (primary) adrenal hyperplasia, adrenal cortex carcinoma, renin-responsive adrenocortical adenoma, and two forms of familial hyperaldosteronism (FH): FH type 1, or glucocorticoid-remediable aldosteronism (GRA) and FH type II. Clinical Presentation PA is present in approximately 10% of the general hypertensive population and is the leading cause of secondary hypertension. The disease is more common in women than men and diagnosis usually occurs between the third and sixth decade of life. Signs and symptoms can include arterial hypertension, which is often moderate to severe and resistant to pharmacologic intervention, as well as hypokalemia (10% to 40% of PA patients), muscle weakness, fatigue, and headache. These features are non-specific for PA and many patients are asymptomatic. Historically, hypokalemia was considered a requisite feature for PA diagnosis; however, normokalemia exists frequently in patients and should not obviate concern for PA.

Diagnosis

Diagnostic confirmation of PA is obtainable through screening, confirmatory tests, and subtype differentiation. As in Cushing’s syndrome, discovery of the underlying etiology ensures proper treatment. Table 85–6 lists the various abnormalities that must be ruled out when suspicion of hyperaldosteronism is high.

CLINICAL PRESENTATION: PRIMARY ALDOSTERONISM

Symptoms

- Patients may complain of muscle weakness, fatigue, paresthesia, and headache.

Signs

- Hypertension
- Tetany/paralysis
- Polydipsia/nocturnal polyuria

Laboratory Tests

- A plasma-aldosterone-to-plasma-renin-activity ratio (PA:PRA), or aldosterone-to-renin ratio (ARR) greater than 20 is suggestive of primary aldosteronism
- Common laboratory findings include suppressed renin activity, elevated plasma aldosterone concentrations, hypernatremia (>142 mEq/L), hypokalemia, hypomagnesemia, elevated bicarbonate concentration (>31 mEq/L), and glucose intolerance

Confirmatory Tests

- Oral or intravenous saline loading, fluorocortisone suppression test (FST), and genetic testing

Initial diagnosis is made through proper screening of patients with suspected primary aldosteronism. Such patients include those with JNC stage two hypertension—appreciating that the prevalence of PA increases with hypertensive severity—and resistant hypertension. Screening for primary aldosteronism is most often done by using the plasma-aldosterone-concentration-to-plasma-renin-activity ratio (PAC:PRA), otherwise known as the aldosterone-to-renin ratio (ARR). An elevated ARR is highly suggestive of PA; however, an optimal cutoff level remains undefined because testing conditions (posture, time, current drug therapy, recent dietary salt intake), patient characteristics, and variable levels of specificity and sensitivity among assays can significantly alter test results. ARR cutoffs of 20 to 40 or 20 with an aldosterone level greater than 15 ng/dL are used most often.
Following a positive ARR screening test, confirmatory testing must be performed to exclude any false-positive cases. Confirmatory tests include the oral sodium loading test, saline infusion test, FST, and the captopril challenge test. Although individual tests can vary in sensitivity, specificity and reliability, any test can be used depending on patient- and institution-specific considerations. FST generally is considered the most reliable, but requires hospitalization. Prior to performing these tests, potassium levels must be normalized and RAS-active agents should be temporarily discontinued, if possible. Positive tests indicate autonomous aldosterone secretion under inhibitory pressures and are diagnostic for PA. After diagnosis, patients with confirmed PA before age 20 or with a family history of PA or strokes before age 40 should undergo genetic testing to properly identify GRA.

Differentiating between an APA and BAH is imperative to formulate a proper treatment plan. Most adenomas are singular and small (<1 cm) and occur more often in the left adrenal gland than the right. Patients with APA generally have more severe hypertension, more profound hypokalemia, and higher plasma and urinary aldosterone levels compared with patients with BAH. Adrenal venous sampling (AVS) provides the most accurate means of differentiating unilateral from bilateral forms of PA. However, AVS is expensive, invasive, and frequently unavailable. CT scanning can detect most adenomas, although an incidentaloma can occasionally cause confusion. If CT scanning is inconclusive, AVS is performed to characterize lateralization.

The underlying abnormality in BAH remains a mystery, but some investigators believe that a hormone factor stimulates the zona glomerulosa, resulting in increased sensitivity to angiotensin II. In contrast to those with an APA, patients with BAH are able to maintain control of the renin-angiotensin system, with little effect following doses of ACTH.

**Therapeutic Management**

### APA-Dependent Aldosteronism

Aldosterone receptor antagonists are the treatment of choice in bilateral cases of primary aldosteronism. Spironolactone, a non-selective aldosterone receptor antagonist, competes with aldosterone for binding at the aldosterone receptor, thus preventing the negative downstream effects of aldosterone receptor activation. Additionally, spironolactone is capable of inhibiting aldosterone synthesis within the adrenal gland; however, the magnitude of this inhibition is relatively small and the effect only occurs at doses above those achieved with therapeutic doses. Spironolactone is available in oral form, with the effect only occurring at doses above those achieved with the angiotensin II receptor antagonist, thus preventing the negative downstream effects of aldosterone, eplerenone, or amiloride plus second-line agents in patients with APA-dependent aldosteronism. Eplerenone has been proven effective in primary essential hypertension; however, its role in the management of hyperaldosteronism has not been established.

Amiloride, a potassium-sparing diuretic, is dosed at 5 mg twice a day up to 30 mg/day if necessary. Amiloride is less effective than spironolactone and often requires additional therapy to adequately control blood pressure. Additional agents useful as second-line options include the calcium channel blockers, ACE inhibitors, and low-dose diuretics such as hydrochlorothiazide, although all lack outcome data evaluation in PA.

Aldosterone synthase inhibitors, currently under development, may offer additional therapeutic options in the future.

### Secondary Aldosteronism

Secondary aldosteronism results from an appropriate response to excessive stimulation of the zona glomerulosa by an extrarenal factor, usually the renin-angiotensin system. Excessive potassium intake can promote aldosterone secretion, as can oral contraceptive use, pregnancy (10 times normal by the third trimester), and menses. Congestive heart failure, cirrhosis, renal artery stenosis, and Bartter syndrome also can lead to elevated aldosterone concentrations.

Treatment of secondary aldosteronism is dictated by etiology. Control or correction of the extrarenal stimulation of aldosterone secretion should resolve the disorder. Medical therapy with spironolactone is the mainstay of treatment until an exact etiology can be located.

### HYPOFUNCTION OF THE ADRENAL GLAND

Primary adrenal insufficiency, or Addison’s disease, most often involves the destruction of all regions of the adrenal cortex. Deficiencies arise in cortisol, aldosterone, and the various androgens and levels of CRH and ACTH increase in a compensatory manor. In developed countries, autoimmune dysfunction is responsible for most cases (80% to 90%), whereas tuberculosis predominates as
the cause in developing countries. Approximately 50% of patients with autoimmune etiologies present with one or more concomitant autoimmune disorders, usually involving other endocrine organs. Autoimmune thyroid disorders (e.g., Hashimoto’s thyroiditis or Graves disease) are the most common, but the ovaries, pancreas, parathyroid gland and organs of the gastrointestinal system can also be affected. This polyglandular failure syndrome, termed autoimmune polyendocrine syndrome (APS), is associated with the idiopathic etiology only and has not been seen with adrenal insufficiency associated with tuberculosis or other invasive diseases. Medications that inhibit cortisol synthesis (ketoconazole), or accelerate cortisol metabolism (phenytoin, rifampin, phenobarbital) can also cause primary adrenal insufficiency.

Secondary insufficiency is characterized by reduced glucocorticoid production secondary to decreased ACTH levels. Low levels of ACTH most commonly result from exogenous steroid use, leading to suppression of the HPA axis and decreased release of ACTH, resulting in impaired androgen and cortisol production. These effects occur with oral, inhaled, intranasal, and topical glucocorticoid administration. Moreover, mirtazapine and progestins, such as medroxyprogesterone acetate and megestrol acetate, have been reported to induce secondary adrenal
insufficiency.58,59 Chronic suppression also can result in atrophy of the anterior pituitary and hypothalamus, impairing recovery of function if the exogenous steroid is reduced. Endogenous secondary insufficiency can occur with tumor development in the hypothalamic-pituitary region. Secondary disease classically presents with normal concentrations of mineralocorticoids since the zona glomerulosa is controlled by the renin-angiotensin system rather than ACTH levels.

Approximately 90% of the adrenal cortex must be destroyed before adrenal insufficiency symptoms will occur.60 Specific etiologies for both primary and secondary insufficiency are listed in Table 85–7. Adrenal hemorrhage can result from multiple etiologies including traumatic shock, coagulopathies, ischemic disorders, and other situations of severe stress, but sepsis is the most common. Symptoms include truncal pain, fever, shaking, chills, hypotension preceding shock, anorexia, headache, vertigo, vomiting, rash, psychiatric symptoms, abdominal rigidity or rebound, and death in 6 to 48 hours if not treated. The most common organ-isms found on autopsy are Neisseria meningitidis, Pseudomonas aeruginosa, Streptococcus pneumoniae, Group A Streptococcus, and Haemophilus influenzae.60,61

### ADDISON’S DISEASE

Distinguishing Addison’s disease from secondary insufficiency is difficult; however, the following guidelines may be helpful:

1. Hyperpigmentation, commonly found in areas of skin exposed to increased friction, is seen only in Addison’s disease because of excess secretion of ACTH and other proopiomelanocortin (POMC) peptides which induce melanocyte-stimulating hormone production. Secondary adrenal insufficiency is fundamentally characterized by deficient ACTH and POMC peptide secretion and a corresponding low level of melanocyte-stimulating hormone production. In fact, some patients with secondary insufficiency may exhibit pale-colored skin secondary to hypopigmentation.

2. Aldosterone secretion usually is preserved in secondary insufficiency.

### Addisons Disease

Addison’s disease will have an abnormal response to the short corticotropin-stimulation test. Plasma ACTH levels are usually 400 to 2000 pg/mL in primary insufficiency, versus low to normal (5 to 50 pg/mL; see Table 85–3) in secondary insufficiency. A normal corticotropin-stimulation test does not rule out secondary adrenal insufficiency, particularly in mild cases.

The short corticotropin-stimulation test, also known as the cosyntropin-stimulation test, can be used to assess patients suspected of hypocortisolism. Patients are given 250 mcg of synthetic ACTH intravenously or intramuscularly, with serum cortisol levels drawn at baseline and 30 to 60 minutes after the injection. A resulting cortisol level ≥18 mcg/dL (500 nmol/L) rules out adrenal insufficiency.62 Because 250 mcg represents a massive supraphysiologic dose, this test can elicit normal, elevated cortisol responses in some cases of mild secondary insufficiency. Thus, some suggest that higher cutoff values (≥22 mcg/dL [≥600 nmol/L]) should be used to prevent false-negative test results.63 Alternatively, a low-dose corticotropic-stimulation test, using 1 mcg of synthetic ACTH, can achieve equivalent results to the standard test and is more sensitive in establishing the diagnosis of secondary insufficiency.64 Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropic-releasing hormone stimulation test.54,62,65

The standard cutoffs described above are of limited use in acutely ill patients.66 Severe infection, trauma, burns, illnesses, or surgery can increase cortisol production by as much as a factor of six, making the recognition of adrenal insufficiency in this population extremely difficult. In the critically ill, a random cortisol level below 15 mcg/dL (415 nmol/L) is suggestive of adrenal insufficiency, whereas a level greater than 34 mcg/dL (940 nmol/L) suggests that adrenal insufficiency is unlikely.67 For patients who fall between these two values, a poor response to corticotropic (less than 9 mcg/dL [250 nmol/L] increase in plasma cortisol from baseline at 30 or 60 minutes) indicates the possibility of adrenal insufficiency and a need for corticosteroid supplementation.68 A severe hypoproteinemic patient (albumin <2.5 g/L) will have markedly lower CBG, which can falsely underestimate the free fraction of cortisol. These patients can benefit from retesting as an outpatient to prevent indefinite glucocorticoid therapy.69

Treatment of Addison’s disease must include adequate patient education, so that the patient is aware of treatment complications, expected outcome, consequences of missed doses, and drug side effects. The agents of choice are hydrocortisone, cortisol, and prednisone, administered twice daily with the treatment objective being the establishment of the lowest effective dose while mimicking the normal diurnal adrenal rhythm.64 Usually a twice-daily dosing schedule is adequate with the dose depending on the agent used.

Endogenous cortisol production varies between 5 and 10 mg/m² per day.67 Hence, the classic 12 to 15 mg/m² per day rule for cortisol supplementation can be excessive in most patients. Recommended starting doses to properly mimic endogenous cortisol production are 15 to 25 mg of hydrocortisone daily, which is roughly equal to 25 to 37.5 mg of cortisone acetate or 2.5 mg of prednisone.64,65,67 The majority of the dose (67%) is given in the morning, whereas the remainder (33%) is given 6 to 8 hours later to duplicate the normal circadian rhythm of cortisol production. Since no laboratory test adequately determines the appropriateness of dosing, the patient’s symptoms should be monitored every 6 to 8 weeks to assess proper glucocorticoid replacement.

*Accounts for approximately 70% of cases.

*Accounts for approximately 20% of cases.
In primary insufficiency, fludrocortisone acetate can be used to supplement mineralocorticoid loss. A dose of 0.05–0.2 mg by mouth once a day is adequate. If parenteral therapy is needed, 2 to 5 mg of deoxycorticosterone trimethylacetate in oil intramuscularly every 3 to 4 weeks can be substituted. Mineralocorticoid replacement attenuates the development of hyperkalemia, but may be unnecessary in all primary cases since glucocorticoids also contribute to mineralocorticoid binding. Adverse effects must be monitored closely. Symptoms include gastric upset, edema, hypertension, hypokalemia, insomnia, excitability, and diabetes mellitus. In addition, patient weight, blood pressure, and electrocardiogram should be monitored regularly.65

In women, the primary source of dehydroepiandrosterone (DHEA) and androgens is the adrenal cortex, specifically the zona reticularis. DHEA is converted to more potent androgens and estrogens in the periphery. Consequently, women with adrenal insufficiency can have decreased libido. DHEA, available as a dietary supplement, has been advocated as an option for female patients with adrenal insufficiency complaining of decreased libido and low energy.66 However, clinical trial data for DHEA is conflicting, and a recent meta-analysis suggests no benefit for sexual well-being.67 Given this limited efficacy and a lack of any standardization among the various commercial products, DHEA should not be used routinely in female patients to improve libido. DHEA may improve mood and well-being in select male and female patients who are already receiving optimal glucocorticoid and mineralocorticoid replacement.

Most adrenal crises occur secondary to glucocorticoid dose reduction or lack of stress-related dose adjustments. Patients receiving corticosteroid-replacement therapy should receive an additional 5 to 10 mg of hydrocortisone shortly before strenuous activities such as exercise.68 Likewise, during times of severe physical stress such as febrile illnesses or injury, patients should be instructed to double their daily dose until recovery.69,70 For major trauma, surgery, or in critically ill patients, larger doses are required. Parenteral therapy should be used for patients experiencing diarrhea or vomiting. In patients with concomitant, newly diagnosed, or uncontrolled hypothyroidism, thyroid replacement should take place only after adequate glucocorticoid replacement as euthyroidism can trigger an adrenal crisis by accelerating cortisol metabolism.54

The end point of therapy is difficult to assess in most patients, but a reduction in excess pigmentation is a good clinical marker. The development of features of Cushing’s syndrome indicates excessive replacement. Treatment of secondary adrenal insufficiency is identical to primary disease treatment, except that mineralocorticoid replacement usually is unnecessary. Patient education is paramount with emphasis placed on the medication regimen and adrenal crisis prevention.

**Acute Adrenal Insufficiency**

Adrenal crisis, or Addisonian crisis, is characterized by an acute adrenocortical insufficiency. Adrenal crisis represents a true endocrine emergency. Anything that increases adrenal requirements dramatically can precipitate an adrenal crisis. Stressful situations, surgery, infection, and trauma all are potential triggering events, especially in the patient with some underlying adrenal or pituitary insufficiency. The most common cause of adrenal crisis is HPA-axis suppression brought on by chronic use of exogenous glucocorticoids and abrupt withdrawal.

Treatment of adrenal crisis involves the administration of parenteral glucocorticoids. Hydrocortisone is the agent of choice owing to its combined glucocorticoid and mineralocorticoid activity. Hydrocortisone is initially administered at a dose of 100 mg intravenously through rapid infusion, followed by a continuous infusion (usually 10 mg/hr) or intermittent bolus of 100 to 200 mg every 24 hours.72 Intravenous administration is continued for 24 to 48 hours, at which time if the patient is stable, oral hydrocortisone can be administered at a dose of 50 mg every 6 to 8 hours, followed by tapering to the individual’s chronic replacement needs. Fluid replacement often is required and can be accomplished with dextrose 5% in normal saline solution (D5NS) at a rate to support blood pressure. During initial treatment for adrenal crisis, mineralocorticoid replacement generally is unnecessary because of hydrocortisone’s mineralocorticoid activity (hydrocortisone 50 mg = fludrocortisone 0.1 mg). If hyperkalemia is present after the hydrocortisone maintenance phase, additional mineralocorticoid supplementation can be achieved with 0.1 mg of fludrocortisone acetate daily.

Patients with adrenal insufficiency should be instructed to carry a card or wear a bracelet or necklace, such as MedicAlert, that contains information about their condition. Patients should also have easy access to injectable hydrocortisone or glucocorticoid suppositories in case of an emergency or during times of physical stress, such as febrile illness or injury.63

**HYPOALDOSTERONISM**

Hypoadosteronism is rare and usually associated with low renin status (hyporeninemic hypoadosteronism), diabetes, complete heart block, or severe postural hypotension, or it can occur postoperatively following tumor removal. Hypoadosteronism can be part of a larger adrenal insufficiency or a standalone defect. In nonsuppressive hypoadosteronism, generalized adrenocortical insufficiency is the most likely etiology (see Addison’s Disease). In selective hypoadosteronism, insufficient aldosterone levels are precipitated by a specific defect in the stimulation of adrenal aldosterone secretion, with 21-hydroxylase deficiency being most common. Pseudohypoadosteronism results from a defect in peripheral
Endocrinologic Disorders

SECTION 8

Loss of female body contour, breast atrophy, and hair recession and include voice deepening, acne, increased muscle mass, menstrual being the dominant feature. Additional coexisting features can include disruptions of the normal cascade of events (see Fig. 85–2). This group of enzyme disorders is collectively referred to as congenital adrenal hyperplasia because of the resultant chronic adrenal stimulation that occurs following enzyme deficiency. The most frequent cause of congenital adrenal hyperplasia is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore, treatment focuses on replacement of the deficient hormone, psychologic support, and surgical repair of the external genitalia in most female patients. Six of the most common enzyme deficiencies are outlined briefly in Table 85–8.

CONGENITAL ADRENAL HYPERPLASIA

Because many enzyme systems are needed to complete the complex cholesterol-to-cortisol pathway, enzyme deficiencies can lead to disruptions of the normal cascade of events (see Fig. 85–2). This group of enzyme disorders is collectively referred to as congenital adrenal hyperplasia because of the resultant chronic adrenal stimulation that occurs following enzyme deficiency. The most frequent cause of congenital adrenal hyperplasia is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore, treatment focuses on replacement of the deficient hormone, psychologic support, and surgical repair of the external genitalia in most female patients. Six of the most common enzyme deficiencies are outlined briefly in Table 85–8.

ADRENAL VIRILISM

Virilism, excessive secretion of androgens from the adrenal gland, commonly occurs as a result of congenital enzyme defects. Depending on the enzyme deficiency, patients accumulate excess levels of a variety of androgens, most notably testosterone. The condition affects females more often than males, with hirsutism being the dominant feature. Additional coexisting features can include voice deepening, acne, increased muscle mass, menstrual abnormalities, clitoral enlargement, redistribution of body fat and loss of female body contour, breast atrophy, and hair recession and crown balding.

Treatment of virilism centers around suppression of the pituitary-adrenal axis with exogenous glucocorticoids. In adults, the usual steroids used are dexamethasone (0.25 to 0.5 mg), prednisone (2.5 to 5 mg), or hydrocortisone (10 to 20 mg).

HIRSUTISM

Women presenting with hirsutism exhibit excess terminal hair growth in an androgen-dependent distribution. Such growth has obvious cosmetic consequences, but also can adversely affect quality-of-life and psychological well-being. Most cases of hirsutism occur in women with some degree of excess androgen production. Androgen excess can be derived from either the ovaries or the adrenal glands, or rarely from pituitary disorders. Polycystic ovarian syndrome (PCOS) is responsible for most cases of ovarian excess and is the most common cause of hirsutism overall. Congenital adrenal hyperplasia accounts for 5% of cases while adrenal and ovarian tumors cause hyperandrogenemia in 0.2% of women.

Cosmetic approaches generally are tried first, with repeated photoepilation offering the greatest long-term success. If these approaches are unsuccessful, subsequent treatment should include pharmacologic intervention. Oral contraceptives are the treatment of choice in most hirsute women, particularly in those requiring concurrent contraception. If oral contraceptives are used, a progestin with low androgen activity (norethindrone, ethynodiol diacetate, or drospirenone) should be chosen. Antiandrogens, including spironolactone and finasteride, can supplement or replace oral contraceptive therapy in women who cannot or choose not to conceive. Antiandrogens can take 6 to 12 months to alleviate hirsutism and treatment should be continued for 2 years, followed by a slow dose reduction. Glucocorticoids, such as dexamethasone, can be used if the androgen source is adrenal, but can induce cushingoid symptoms even in doses of 0.5 mg/day.

Gonadotropin-releasing hormone can be an effective adjunct or alternative to oral contraceptives if the source of androgen is ovarian. However, these products generally are not recommended due to excessive costs, injectible-only routes of administration, and adverse effects resulting from estrogen deficiency. Additionally, insulin sensitizers, such as metformin or thiazolidinediones, can show modest improvement in women with PCOS.

Efllornithine hydrochloride, an irreversible ornithine decarboxylase inhibitor, moderately reduces the rate of hair growth but does

not remove hair already present. The drug is available as a topical cream that is applied as a thin layer to the affected area twice daily, at least 8 hours apart. Reduction in unwanted hair can be noted within 6 to 8 weeks with a maximal effect at 8 to 24 weeks. Skin irritation can occur that resolves on discontinuation.

**CLINICAL CONTROVERSY**

Some clinicians believe that the usual starting doses for glucocorticoid supplementation are high and unnecessarily increase a patient’s risk for adverse outcomes such as osteoporosis.

**PRINCIPLES OF GLUCOCORTICOID ADMINISTRATION**

Originally, the term glucocorticoid was given to these agents to describe their glucose-regulating properties. However, carbohydrate metabolism is only one of the myriad of effects exhibited by steroids. The activity produced by these drugs is a function of the agent and dose prescribed.

The mechanism of action of glucocorticoids is complex and not fully known. The glucocorticoid enters the cell through passive diffusion and binds to its specific receptor. Between 5,000 and 100,000 receptors exist in each cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and 100,000 receptors exist in each cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and therefore elicit a wide variety of biologic effects.

Following receptor binding, a structural change occurs in the receptor, known as activation. After activation, the receptor-steroid complex binds to deoxyribonucleic acid sites in the cell called glucocorticoid response elements (GREs). This binding stimulates or inhibits transcription of nearby genes.

Pharmacokinetic properties of the glucocorticoids vary by agent and route of administration. In general, most orally-administered steroids are well absorbed. Water-soluble agents are more rapidly absorbed following intramuscular injection than are lipid-soluble agents. Intravenous administration is recommended when a quick onset of action is needed. A summary of these agents is provided in Table 85–9.

In addition to causing iatrogenic Cushing’s syndrome, systemic steroids can lead to increased susceptibility to infection, osteoporosis, sodium retention with resultant edema, hypokalemia, hypomagnesemia, cataracts, peptic ulcer disease, seizures, and generalized suppression of the HPA-axis. Long-term complications tend to be insidious and less likely to respond to steroid withdrawal. Suppression of the HPA-axis is a major concern whenever systemic steroids are tapered or withdrawn. Single doses of glucocorticoids can prevent the axis from responding to major stressors for several hours. In general, steroid administration at a high dose for long periods of time causes suppression of the axis. However, the possibility of suppression occurs any time the patient is exposed to supraphysiologic doses of a steroid. Symptoms of steroid withdrawal resemble those seen in a patient with adrenocortical deficiency.

A variety of recommendations for steroid tapering are available. In general, patients who have been on long-term steroid therapy will need to be gradually withdrawn toward physiologic doses over months. On average, the normal adult produces approximately 10 to 30 mg of cortisol per day with the peak concentration occurring around 8:00 AM. As the steroid or steroid-equivalent dose approaches the 20- to 30-mg level, the taper should be slowed and the patient checked for axis function. The primary modes to test HPA integrity are the ACTH test, either high- or low-dose, or a morning (8:00 AM) serum cortisol. A normal morning serum cortisol (>20 mcg/dL) or a normal ACTH test indicates that daily steroid maintenance therapy may be discontinued. If morning serum cortisol is between 3 and 20 mcg/dL, the ACTH- or CRH-stimulation test can be useful in the assessment of pituitary-adrenal function. A morning cortisol less than 3 mcg/dL indicates axis suppression and the need for continued replacement therapy. Suppression can persist for up to a year in some patients. Caution should be used to prevent disease exacerbation during the steroid taper and to avoid the need for rebolusation with another course of high-dose steroids.

Alternate day therapy (ADT) regimens have been promoted by some as a means to lessen the impact of prolonged steroid administration. ADT theoretically minimizes the hypothalamic-pituitary suppression as well as some of the adverse effects seen with once-daily therapy. This hypothetical advantage may be especially pertinent in treating children and young adults, in whom growth suppression is a major concern. ADT is not recommended for initial management, but rather in the management of the stabilized patient who needs long-term therapy. The patient is exposed to “on” and “off” days, with the “on” day dose gradually increased corresponding with a dose-reduction in the “off” day dose over a period of 14 days. After two weeks, no medication is taken on “off” days. Not all patients will have equivalent disease control on ADT, and it should be avoided in certain indications.

**CLINICAL CONTROVERSY**

Some clinicians advocate thrice-daily dosing of glucocorticoids over twice-daily dosing as a means to more closely mimic physiologic variations in cortisol. Limited comparative data has favored three dose regimens, but most studies have serious methodologic flaws. If a thrice-daily regimen is used, the second dose should be administered at noon, followed by a third dose approximately 4 to 6 hours later.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Successful glucocorticoid therapy involves counseling and monitoring the patient, as well as recognizing complications of therapy (Table 85–10). The risk-to-benefit ratio of glucocorticoid administration should always be considered, especially with concurrent disease states such as hypertension, diabetes mellitus, peptic ulcer disease, and uncontrolled systemic infections.

BAH: bilateral adrenal hyperplasia 
CBG: corticosteroid-binding globulin 
CHD: coronary heart disease 
CrCl: creatinine clearance 
CRH: corticotropin-releasing hormone 
CT: computed tomography 
D₅NS: dextrose 5% in normal saline solution 
DDT: dichlorodiphenyltrichloroethane 
DST: dexamethasone suppression test 
FH: familial hyperaldosteronism 
FST: fludrocortisone suppression test 
GRA: glucocorticoid-remediable aldosteronism 
GRE: glucocorticoid response element 
HPA: hypothalamic-pituitary-adrenal 
IPSS: inferior petrosal sinus sampling 
IRMA: immunoradiometric assay 
JNC: Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure 
JVS: jugular venous sampling 
MRI: magnetic resonance imaging 
PAC:PRA: plasma-aldosterone-concentration–to–plasma-renin-activity (ratio) 
PA: primary aldosteronism 
RIA: radioimmunoassay 
RU-486: mifepristone 
UFC: urine free cortisol

### REFERENCES

Pharmacologic therapy for acromegaly should be considered when surgery and irradiation are contraindicated, when there is poor likelihood of surgical success, when rapid control of symptoms is needed, or when other treatments have failed to normalize growth hormone (GH) and insulin-like growth factor 1 (IGF-1) concentrations. Pharmacotherapy for acromegaly using dopamine agonists provides advantages of oral dosing and reduced cost compared to somatostatin analogs and pegvisomant. However, dopamine agonists effectively normalize IGF-1 concentrations in only 10% of patients. Therefore, somatostatin analogs remain the mainstay of therapy.

Blood glucose concentrations should be monitored frequently in the early stages of somatostatin analog therapy in all acromegalic patients.

Pegvisomant appears to be the most effective agent for normalizing IGF-1 concentrations. However, further study is needed to determine the long-term safety and efficacy of this agent for the treatment of acromegaly.

Recombinant GH is currently considered the mainstay of therapy for treatment of children with growth hormone-deficient (GHD) short stature. Prompt diagnosis of GHD and initiation of replacement therapy with recombinant GH is crucial for optimizing final adult heights.

All GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/wk.

Pharmacologic agents that antagonize dopamine or increase the release of prolactin can induce hyperprolactinemia. Discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalize serum prolactin concentrations.

Cabergoline appears to be more effective than bromocriptine for the medical management of prolactinomas and offers the advantage of less frequent dosing and decreased adverse events.

Although preliminary data do not suggest cabergoline has significant teratogenic potential, cabergoline is not recommended for use during pregnancy, and patients receiving cabergoline who plan to become pregnant should discontinue the medication as soon as pregnancy is detected.

Pharmacologic treatment of panhypopituitarism consists of glucocorticoids, thyroid hormone preparations, sex steroids, and recombinant GH, where appropriate, as lifelong replacement therapy.

In the 1950s, Geoffrey Harris and his colleagues uncovered the physiologic importance of pituitary hormones and proposed the theory of neurohormonal regulation of the pituitary by the hypothalamus. Today the pituitary gland is recognized for its essential role in body homeostasis, and for this reason it is often referred to as the “master gland.” The hypothalamus and the pituitary gland are closely connected, and together they provide a means of communication between the brain and many of the body’s endocrine organs. The hypothalamus uses nervous input and metabolic signals from the body to control the secretion of pituitary hormones that regulate growth, thyroid function, adrenal activity, reproduction, lactation, and fluid balance.

The hypothalamus (Fig. 86–1) is a small region at the base of the brain that receives autonomic nervous input from different areas of the body to regulate limbic functions, food and water intake, body temperature, cardiovascular function, respiratory function, and diurnal rhythms. In addition, the hypothalamus controls the release of hormones from the anterior and posterior regions of the pituitary gland. Neurons in the hypothalamus produce vasopressin and oxytocin and make many hormone-releasing factors that stimulate or inhibit the release of trophic hormones. At the base of the hypothalamus, a projection known as the median eminence is rich with nerve axons and blood vessels and provides both chemical and physical connections between the hypothalamus and the pituitary gland.

The pituitary gland, also referred to as the hypophysis, is located at the base of the brain in a cavity of the sphenoid bone known as the sella turcica. The pituitary is separated from the brain by an extension of the dura mater known as the diaphragma sella. The pituitary is a very small gland, weighing between 0.4 and 1 g in adults. It is divided into two distinct regions, the anterior lobe, or adenohypophysis, and the posterior lobe, or the neurohypophysis (see Fig. 86–1).

The posterior pituitary gland secretes two major hormones: oxytocin and vasopressin (antidiuretic hormone) (Table 86–1).
Endocrinologic Disorders

Inhibiting and releasing hormones synthesized in the neurons of the hypothalamus contain hormones. The median eminence of the hypothalamus contains a role in uterine contraction during parturition. Vasopressin is primarily regulated by indirect nervous stimulation but rather inhibitory hormone) inhibits the secretion of prolactin. Prolactin stimulates anterior pituitary release of TSH and prolactin, corticotropin-releasing hormone (CRH) stimulates anterior pituitary release of ACTH, growth hormone-releasing hormone (GHRH) stimulates anterior pituitary release of GH, and gonadotropin-releasing hormone (GnRH) stimulates anterior pituitary release of LH and FSH. Hypothalamic release of somatostatin inhibits release of GH, and hypothalamic release of dopamine (prolactin inhibitory hormone) inhibits the secretion of prolactin. Prolactin differs from the other anterior lobe hormones in that an inhibiting factor, rather than a stimulating factor, is primarily responsible for controlling its secretion. In the absence of hypothalamic input, an excess of prolactin is produced, whereas a deficiency state of other anterior pituitary hormones results. Physiologic regulation and action of anterior and posterior pituitary hormones are summarized in Table 86–1.

GROWTH HORMONE

GH has direct antinsulin effects on lipid and carbohydrate metabolism. GH decreases utilization of glucose by peripheral tissues, increases lipolysis, and increases muscle mass. GH also stimulates gluconeogenesis in hepatocytes, impairs tissue glucose uptake, decreases insulin-receptor sensitivity, and impairs post-receptor insulin action. The growth-promoting effects of GH are largely mediated by insulin-like growth factors (IGFs) also known as somatomedins. GH stimulates the formation of insulin-like growth factor 1 (IGF-1) in the liver as well as in other peripheral tissues. This anabolic peptide acts as a direct stimulator of cell proliferation and growth. There are two types of insulin-like growth factors: IGF-1 and IGF-2. IGF-1 regulates growth to some extent before, and largely after, birth. In contrast, IGF-2 is thought to primarily regulate growth in utero. GH is secreted by the anterior pituitary in a pulsatile fashion, with several short bursts that occur mostly at night. Because of the short half-life of GH in the plasma (~30 minutes), measurements of circulating GH concentrations throughout the waking hours usually are very low or undetectable. Daytime GH pulses are most likely to occur after meals, following exercise, or during periods of stress. The greatest amount of GH secretion occurs during the night within the first 1 to 2 hours of slow-wave sleep (stage III or IV). Secretion of GH is lowest during infancy, increases slightly during childhood, reaches its peak during adolescence, and then begins to gradually decline during the middle-age years.

GROWTH HORMONE EXCESS

Acromegaly is a pathologic condition characterized by excessive production of GH. This is a rare disorder that affects approximately 50 to 70 adults per million. Gigantism, which is even more rare than acromegaly, is the excess secretion of GH prior to epiphyseal closure in children. Patients diagnosed with acromegaly are reported to have a 2- to 3-fold increase in mortality, usually related to cardiovascular, respiratory, or neoplastic disease. Most patients are middle-aged at the time of diagnosis, and this disorder does not appear to affect one sex to a greater extent than the other. The most common cause of excess GH secretion in acromegaly is a GH-secreting pituitary adenoma, accounting for approximately 98% of all cases. Rarely, acromegaly is caused by ectopic GH-secreting adenomas, GH cell hyperplasia, or excess GHRH secretion, or is one of the manifestations of multiple endocrine neoplasia syndrome type 1, McCune-Albright’s syndrome, or the Carney complex, all very rare hypersecretory endocrinopathies.

Data from Amar and Weiss, Cutler, and Molitch.

The clinical signs and symptoms of acromegaly develop gradually over an extended period of time. In fact, because of the subtle and slowly developing changes in physical appearance caused by GH excess, most patients are not definitively diagnosed with acromegaly until 7 to 10 years after the presumed onset of excessive GH secretion. Excessive secretion of GH and IGF-1 adversely affects several organ systems. Almost all acromegalic patients will present with physical signs and symptoms of soft-tissue overgrowth. Table 86–2 summarizes the classic clinical presentation of patients with acromegaly. Some patients with acromegaly present with only a few of these classic signs and symptoms, making recognition of this disease extremely difficult.
The diagnosis of acromegaly is based on a combination of diagnostic tests and clinical signs and symptoms. Random measures of plasma GH levels are not usually dependable because of the pulsatile pattern of release. The oral glucose tolerance test (OGTT) is commonly used as an important diagnostic tool. Postprandial hyperglycemia inhibits the secretion of GH for at least 1 to 2 hours. Therefore, an oral glucose load would be expected to suppress GH concentrations. However, patients with acromegaly continue to secrete GH during the OGTT. Because GH stimulates the production of IGF-1, serum IGF-1 concentrations can also be measured to aid in the diagnosis of acromegaly. Circulating IGF-1 is cleared from the body at a much slower rate than is GH, and measurements can be collected at any time of the day to identify patients with GH excess. Current criteria for the diagnosis of acromegaly include failure of GH suppression <1 mcg/L following an OGTT in the presence of elevated IGF-1 serum concentrations. With the development of more sensitive GH and IGF-1 assays, the cutoff value for diagnosis of acromegaly will likely decrease in the future. Insulin-like growth factor 1 binding protein 3 (IGFBP-3) also can be measured because it is positively regulated by GH and binds to circulating IGF-1 with high affinity. This test may be useful in monitoring response to therapy. Computed tomography and magnetic resonance imaging of the pituitary are important diagnostic tests to confirm the presence of a pituitary adenoma.

**TABLE 86-2  Clinical Presentation of Acromegaly**

| Section 8: Endocrinologic Disorders |

**General**
The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 7 to 10 years.

**Symptoms**
The patient may complain of symptoms related to local effects of the growth hormone (GH)-secreting tumor, such as headache and visual disturbances. Other symptoms related to elevated GH and insulin-like growth factor-1 (IGF-1) concentrations include excessive sweating, neuropathies, joint pain, and paresthesias.

**Signs**
The patient may exhibit coarsening of facial features, increased hand volume, increased ring size, increased shoe size, an enlarged tongue, and various dermatologic conditions.

**Laboratory tests**
The patient’s GH concentration will be >1 mcg/L following an oral glucose tolerance test (OGTT) and IGF-1 serum concentrations will be elevated. Glucose intolerance may be present in up to 50% of patients.

**Additional clinical sequelae**
- Cardiovascular diseases such as hypertension, coronary heart disease, cardiomyopathy, and left ventricular hypertrophy are common in patients with acromegaly.
- Osteoarthritis and joint damage develops in up to 90% of acromegalic patients.
- Respiratory disorders and sleep apnea occur in up to 60% of acromegalic patients.
- Type 2 diabetes develops in approximately 25% of acromegalic patients.
- Patients with acromegaly may have an increased risk for development of esophageal, colon, and stomach cancer.

**TREATMENT**

**Acromegaly**
The primary treatment goals for patients diagnosed with acromegaly are to reduce GH and IGF-1 concentrations, improve the clinical signs and symptoms of the disease, and decrease mortality. Many clinicians define biochemical control of acromegaly as suppression of GH concentrations to <1 mcg/L after a standard OGTT in the presence of normal IGF-1 serum concentrations. The treatment of choice for most patients with acromegaly is transsphenoidal surgical resection of the GH-secreting adenoma. Postsurgical cure rates have been reported to range from 50% to 90%, depending on the type of adenoma and the expertise of the neurosurgeon. Complications of transsphenoidal surgery are relatively infrequent and include cerebrospinal fluid leak, meningitis, arachnoiditis, diabetes insipidus, and pituitary failure. For patients who are poor surgical candidates, those who have not responded to surgical interventions, or others who refuse surgical treatment, radiation therapy may be considered. Radiation, however, may take several years to relieve the symptoms of acromegaly.

Because neither radiation therapy nor surgery will cure all patients with acromegaly, adjunct drug therapy is often needed to control symptoms.

**PHARMACOLOGIC THERAPY**

1. Drug therapy should be considered for acromegalic patients in whom surgery and irradiation are contraindicated, when there is poor likelihood of surgical success, when rapid control of symptoms is indicated, or when other treatments have failed to normalize GH and IGF-1 concentrations. Pharmacologic treatment options include dopamine agonists, somatostatin analogs, and the GH receptor antagonist pegvisomant. Dopamine agonists such as bromocriptine and cabergoline are effective in a small subset of patients and provide the advantages of oral dosing and reduced cost. Somatostatin analogs are more effective than dopamine agonists, reducing GH concentrations and normalizing IGF-1 in approximately 50% to 60% of patients. Pegvisomant, a GH receptor antagonist, is highly effective in normalizing IGF-1 concentrations in up to 97% of patients. However, additional long-term data are needed to establish the safety and efficacy of pegvisomant in the management of acromegaly.

**DOPAMINE AGONISTS**

2. In normal healthy adults, dopamine agonists cause an increase in GH production. However, when these agents are given to patients with acromegaly, there is a paradoxical decrease in GH production. Most clinical experience with the use of dopamine agonists in acromegaly is with bromocriptine. Other agents such as pergolide, cabergoline, and lisuride also have been used. Bromocriptine is a semisynthetic ergot alkaloid that acts as a dopamine-receptor agonist. Most trials assessing the efficacy of bromocriptine in the treatment of acromegaly were conducted in the 1970s and early 1980s. These studies determined that certain subsets of acromegalic patients have a favorable response to drug therapy with bromocriptine. These patients include individuals with high circulating concentrations of prolactin and patients who experience GH suppression following a single 2.5-mg dose of bromocriptine, known as a bromocriptine challenge. A review evaluating 34 studies concluded that therapy with bromocriptine was effective in suppressing mean serum GH levels to <5 mcg/L in approximately 20% of patients. Only 10% of patients experience normalization of IGF-1 concentrations with bromocriptine therapy, but >50% of patients treated with bromocriptine experience improvement in acromegalic symptoms.

In the United States, bromocriptine is commercially available as 2.5-mg oral tablets and 5-mg oral capsules. In acromegalic patients, significant reductions in GH concentrations are observed within 1 to 2 hours of oral dosing. This effect persists for at least 4 to 5 hours. An overall clinical response in acromegalic patients typically occurs
after 4 to 8 weeks of continuous bromocriptine therapy. For treatment of acromegaly, bromocriptine is initiated at a dose of 1.25 mg at bedtime and is increased by 1.25-mg increments every 3 to 4 days as needed.\textsuperscript{20,21} Doses as high as 86 mg/day have been used for treatment of acromegaly, but clinical studies have shown that doses >20 or 30 mg daily do not offer additional benefits in the suppression of GH.\textsuperscript{20,21} When used for treatment of acromegaly, the duration of action of bromocriptine is shorter than that for treatment of hyperprolactinemia. Therefore, the total daily dose of bromocriptine should be divided into three or four doses.\textsuperscript{19,21}

The most common adverse effects of bromocriptine therapy include central nervous system (CNS) symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, or diarrhea also are very common. Some patients may need to take bromocriptine with food to decrease the incidence of adverse gastrointestinal effects. Most adverse effects are seen early in the course of therapy and tend to decrease with continued treatment.\textsuperscript{21} Bromocriptine may cause thickening of bronchial secretions and nasal congestion. Rare cases of psychiatric disturbances, pleural diseases, and an erythromelalgic syndrome (painful paroxysmal dilation of the blood vessels in the skin of the feet and lower extremities) have been reported with bromocriptine use. These conditions appear to be associated with higher doses and prolonged duration of therapy.\textsuperscript{20,21}

Bromocriptine generally should be discontinued if a woman becomes pregnant while taking the drug. Surveillance of women who took bromocriptine throughout pregnancy does not suggest that bromocriptine is associated with an increased risk for birth defects.\textsuperscript{21} If a woman becomes pregnant while taking bromocriptine, the risks and benefits of therapy should be fully considered. In most cases, the benefits of successful therapy outweigh the risks, and bromocriptine therapy should be continued if it is effective in improving symptoms and reducing elevated GH concentrations.

Other dopamine agonists that have been used to treat acromegaly include pergolide, cabergoline, lisuride, and quinagolide. Cabergoline may be especially useful in patients with pituitary tumors who secrete both prolactin and GH.\textsuperscript{21,22} Quinagolide, a dopamine agonist available in Europe, has been shown to be more effective than both bromocriptine and cabergoline in normalizing GH and IGF-1 values in acromegalic patients.\textsuperscript{19} Because of the potential cost advantages and convenience of oral administration, dopamine agonists are often considered for treatment of acromegaly prior to initiation of somatostatin analogs. However, the availability of long-acting somatostatin analogs has made these agents more attractive for first-line treatment of acromegaly.

### SOMATOSTATIN ANALOGS

Octreotide and lanreotide are long-acting somatostatin analogs that are more potent in inhibiting GH secretion than endogenous somatostatin.\textsuperscript{21,24} These agents also suppress the LH response to GnRH; decrease splanchnic blood flow; and inhibit secretion of insulin, vasoactive intestinal peptide (VIP), gastrin, secretin, motilin, serotonin, and pancreatic polypeptide.

Octreotide (Sandostatin) injection is commercially available in the United States for subcutaneous or intravenous administration. A long-acting intramuscular formulation of octreotide (Sandostatin LAR) is available for monthly administration. In addition to the treatment of acromegaly, octreotide has many other therapeutic uses, including the treatment of carcinoid tumors, vasoactive intestinal peptide-secreting tumors (VIPomas), gastrointestinal fistulas, variceal bleeding, diarrheal states, and irritable bowel syndrome.

The efficacy of octreotide for treatment of acromegaly has been determined by two major multicenter trials.\textsuperscript{25,26} These studies determined that drug therapy with octreotide suppresses mean serum GH concentrations to <5 mcg/L and normalizes serum IGF-1 concentrations in 50% to 60% of acromegalic patients. Octreotide also is beneficial in reducing the clinical signs and symptoms of acromegaly. In a 6-month multicenter trial, 70% of patients experienced significant relief of headaches.\textsuperscript{26} In some patients, relief of headache symptoms occurred within minutes of octreotide administration. In addition, middle-finger circumference was reduced significantly, and 50% to 75% of patients experienced improvement in symptoms of excessive perspiration, fatigue, joint pain, and cystic acne. Long-term follow-up of patients treated with octreotide LAR for up to 9 years showed octreotide therapy to be safe and effective for long-term use in acromegalic patients.\textsuperscript{27} Octreotide also has been shown to improve the cardiovascular manifestations of acromegaly and to halt pituitary tumor growth, with some patients experiencing tumor regression.\textsuperscript{25–28} Data from more recent studies indicate that shrinkage of pituitary tumor mass during octreotide therapy occurs in approximately 50% of patients.\textsuperscript{29}

The pharmacodynamic effects of long-acting octreotide are similar to those of subcutaneously administered octreotide. Single monthly doses of long-acting octreotide have been shown to be at least as effective as daily doses of 300 or 600 mcg of subcutaneous octreotide administered in divided doses 3 times daily in normalizing IGF-1 levels and maintaining suppression of mean serum GH concentrations.\textsuperscript{30} A large multicenter trial evaluating the efficacy of long-acting octreotide in acromegalic patients who previously had responded to subcutaneously administered octreotide reported suppression of GH concentrations to <5 mcg/L in 94% of patients and normalization of IGF-1 in 66% of patients following 1 year of therapy.\textsuperscript{31}

Response to long-term therapy with octreotide is related to the presence and increased quantity of functioning somatostatin receptors located in the pituitary adenoma.\textsuperscript{26} Identification of patients who most likely will respond to octreotide, prior to initiation of therapy, is important when considering the high cost of this medication and the inconvenience of subcutaneous or intramuscular drug administration. Suppression of serum GH concentrations after a single 50-mcg dose of octreotide has been used to predict a favorable long-term response to octreotide therapy.\textsuperscript{32,33}

The initial dose of octreotide for treatment of acromegaly is 100 mcg administered every 8 hours.\textsuperscript{18,20,24} Some clinicians recommend a starting dose of 50 mcg every 8 hours, then increasing the dose to 100 mcg every 8 hours after 1 week, to improve the patient’s tolerance of adverse gastrointestinal effects. The dose can be increased by increments of 50 mcg every 1 to 2 weeks based on mean serum GH and IGF-1 concentrations. Patients who experience a significant rise in GH prior to the end of the 8-hour dosing interval may benefit from decreasing the dosing interval to every 4 to 6 hours. Although doses as high as 1,500 mcg/day have been used, doses >600 mcg daily generally do not offer additional benefits, and most patients are adequately managed with 100 to 200 mcg 3 times daily.\textsuperscript{25–28} Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy can be converted to the long-acting depot form of octreotide. The initial dose of long-acting octreotide is 20 mg administered intramuscularly in the gluteal region every 28 days. Steady-state serum concentrations are not obtained until after 3 months of therapy. Therefore, dosage adjustments for long-acting octreotide should not be considered until after this time. Some patients may require additional subcutaneous injections during the initial dose-titration phase in order to control symptoms. Long-acting octreotide doses >30 mg every 4 weeks have not been studied. A long-acting, intramuscular formulation of lanreotide (lanreotide LA) for twice monthly administration has been available in Europe for many years. Recently, a new formulation of lanreotide (Somatuline Depot) was approved for use
in the United States for monthly deep subcutaneous administration. The efficacy of this preparation of lanreotide for the treatment of acromegaly has been evaluated in several prospective multicenter clinical trials involving treatment-experienced patients who were switched from intramuscular octreotide LAR or intramuscular lanreotide LA to monthly deep subcutaneous lanreotide.34–36 These studies have determined that deep subcutaneous lanreotide suppresses mean serum GH concentrations to <5 mcg/L and normalizes serum IGF-1 concentrations in acromegalic patients to a similar extent as octreotide LAR and lanreotide LA. A 4-year follow-up of 23 patients treated with monthly deep subcutaneous lanreotide reported the drug to be well tolerated during long-term therapy with mean serum GH concentrations <5 mcg/L in 62% of patients and normalization of serum IGF-1 concentrations in 43% of patients.37 Well-designed trials directly comparing the efficacy of intramuscular octreotide LAR to deep subcutaneous lanreotide are currently lacking. However, these two agents are generally regarded to have comparable efficacy.36

Lanreotide (Somatuline Depot) is commercially available in the United States as 60-mg, 90-mg, and 120-mg prefilled syringes. In contrast to octreotide LAR, lanreotide injection does not need to be reconstituted prior to administration. The initial recommended dose of lanreotide is 90 mg given by deep subcutaneous injection in the superior external quadrant of the buttock every 28 days. Injection sites should be alternated between the left and right side. The initial dose should be reduced to 60 mg every 28 days for patients with moderate or severe renal or hepatic impairment. After 3 months of therapy, the dose may then be titrated based on serum GH concentrations, serum IGF-1 concentrations, and control of clinical signs and symptoms of acromegaly.36 Long-acting deep subcutaneous lanreotide injection in doses >120 mg every 28 days has not been studied.

The most common adverse effects of somatostatin analog therapy are gastrointestinal disturbances such as diarrhea, nausea, abdominal cramps, malabsorption of fat, and flatulence.16,23 Gastrointestinal adverse effects occur in approximately 75% of patients but usually subside within 10 to 14 days of continued treatment.23 Octreotide has been reported to cause injection-site pain (4%–31%),conduction abnormalities and arrhythmias (9%), biochemical hypothyroidism (2%–12%), biliary tract disorders (4%–50%), and abnormalities in glucose metabolism (2%–18%).20,21 Lanreotide has been reported to cause injection-site reactions (9%), sinus bradycardia (3%), hypertension (5%), biliary tract disorders (20%), and abnormalities in glucose metabolism (7%).25

Somatostatin analogs also inhibit cholecystokinin release and gallbladder motility, predisposing patients to the development of cholelithiasis.23 The development of gallstones is a long-term adverse effect of somatostatin analog therapy and is largely dependent on geographic factors, dietary habits, and length of therapy.20,24 The incidence of gallstones in acromegalic patients receiving octreotide and lanreotide increases with length of therapy and has been reported to range from 20% to 50%.24–26 However, most patients are asymptomatic, and the diagnosis of cholelithiasis usually is made following an ultrasonographic study that is not prompted by patient symptoms. It has been estimated that only 1% of patients will develop symptomatic gallstones during 1 year of octreotide treatment.24 Because somatostatin analog-induced gallstones usually are present without clinical symptoms, prophylactic cholecystectomy or medical therapy with ursodeoxycholic acid for acromegalic patients with asymptomatic gallstones usually is not recommended.38,39 A small number of studies have suggested that the incidence of gallstone development may be lower with long-acting octreotide compared to subcutaneous octreotide.30,31 However, further studies are needed to confirm this observation.

The effect of somatostatin analogs on glucose metabolism in patients with acromegaly is multifactorial. Decreases in serum GH concentrations induced by somatostatin analogs should result in decreased hepatic gluconeogenesis and increased insulin-receptor sensitivity. However, somatostatin analogs also decrease insulin secretion and increase IGFBP-1, which is known to inhibit the insulin-like effects of IGF-1. In addition, somatostatin analogs delay the gastrointestinal absorption of glucose, which may further alter glucose metabolism in acromegalic patients.37 Small studies conducted in acromegalic patients receiving octreotide have reported improvement in insulin sensitivity as well as impaired insulin secretion.38,39 Risk factors associated with worsening glucose tolerance included female sex and elevated baseline insulin values. Although somatostatin analogs appear to have a beneficial effect on glucose tolerance in most patients, glucose determinations should be obtained frequently in the early stages of therapy in all acromegalic patients.

### GROWTH HORMONE RECEPTOR ANTAGONIST

Pegvisomant (Somavert) is a genetically engineered GH derivative that binds to, but does not activate, GH receptors and inhibits IGF-1 production by the liver. This agent is different from other medications used in the management of acromegaly because it does not inhibit GH production; rather, it blocks the physiologic effects of GH on target tissues. Therefore, GH concentrations remain elevated during therapy, and response to treatment is evidenced by a reduction in IGF-1 concentrations. Unlike somatostatin analogs, the pharmacologic activity of pegvisomant does not depend on the presence and quantity of somatostatin receptors in the pituitary tumor.40 Studies evaluating the clinical efficacy of pegvisomant in acromegalic patients have reported a dose-dependent normalization of IGF-1 concentrations in 54% to 89% of patients after 12 weeks of therapy and in 97% of patients after 1 year of therapy.40,41 Significant improvements in the clinical signs and symptoms of acromegaly were reported and persisted throughout the 1-year treatment period.40 Adverse effects include injection-site pain, gastrointestinal complaints such as nausea and diarrhea, and flu-like symptoms. Significant elevations in hepatic aminotransferase concentrations, which are generally reversible upon discontinuation of the drug, have been reported in approximately 25% of patients.16,42 As a result, hepatic function tests should be monitored very closely during therapy as outlined in the product labeling, and the drug should be used with caution in patients with baseline elevations in hepatic aminotransferase concentrations. GH concentrations increased significantly during the first 6 months of therapy. Tumor growth has been reported in a small number of patients and there are theoretical concerns that persistently elevated GH concentrations may stimulate tumor growth or result in other unfavorable long-term effects.

Pegvisomant is commercially available in the United States for daily subcutaneous use. The first dose should be administered under the supervision of a physician as a 40-mg loading dose. Subsequent doses are self-administered by the patient starting at a dose of 10 mg daily. The dose can be adjusted in 5-mg increments based on serum IGF-1 concentrations every 4 to 6 weeks, up to a maximum daily dose of 30 mg.43

Based on the available data, pegvisomant appears to be among the most effective agents for normalizing IGF-1 serum concentrations. However, it is very expensive and further study is needed to determine the long-term safety and efficacy of pegvisomant in the treatment of acromegaly. Current guidelines for acromegaly management suggest pegvisomant therapy for patients who have failed to achieve normalization of IGF-1 serum concentrations with other treatments.44
COMBINATION THERAPY

Several small studies have suggested that combination therapy with octreotide and dopamine agonists (bromocriptine or cabergoline) or octreotide and pegvisomant may be more beneficial than monotherapy with either drug alone.\textsuperscript{20,23,44} Because of the potential for additive adverse effects, combination therapy should be considered as a therapeutic option only for refractory patients who have not fully responded to monotherapy.\textsuperscript{16}

PHARMACOECONOMIC CONSIDERATIONS

Cost-effectiveness comparisons of the various treatment options for patients with acromegaly have not been performed. Considering that approximately 40% of patients are not completely cured after transphenoidal surgery, pharmacologic treatment often becomes necessary. Bromocriptine and cabergoline are available as oral dosage forms and are considerably less expensive than octreotide, lanreotide, and pegvisomant. However, these agents are not effective in the majority of patients. Long-acting octreotide and lanreotide offer a convenient method of once-monthly administration for acromegalic patients, and may result in improved patient compliance, quality of life, and overall disease management. Pegvisomant appears to be the most effective agent for normalizing IGF-1 concentrations and may be useful in patients who are intolerant to or have not responded to therapy with dopamine agonists or somatostatin analogs. However, pegvisomant is significantly more expensive than long-acting octreotide or lanreotide and requires daily subcutaneous injections. Long-term studies evaluating the safety of pegvisomant are needed to clearly define its role in the management of acromegaly. The drug therapy of choice for an acromegalic patient should be determined by careful consideration of several patient-specific factors, including clinical response, compliance, tolerability, and cost of therapy.

CONCLUSIONS

Acromegaly is a chronic debilitating disease characterized by excess GH secretion most commonly caused by a GH-secreting pituitary adenoma. Transphenoidal surgical resection of the adenoma is the current treatment of choice for most patients with acromegaly. Patients who are poor surgical candidates may receive radiation therapy or long-term pharmacologic therapy. Drug therapy options within the United States for acromegaly include dopamine agonists, somatostatin analogs, and pegvisomant. Figure 86–2 shows a treatment algorithm for the management of acromegaly.\textsuperscript{9,16}

GROWTH HORMONE DEFICIENCY

Short stature is a condition that is commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group. It has been estimated that more than 1.8 million children in the United States can be characterized as having short stature. Short stature is a very broad term describing a condition that may be the result of many different causes. A true lack of GH is among the least common causes and is known as growth hormone-deficient (GHD) short stature. Absolute GH deficiency is a congenital disorder that can result from various genetic abnormalities, such as GHRH deficiency, GH gene deletion, and developmental disorders including pituitary aplasia or hypoplasia. GH insufficiency is an acquired condition that can result secondary to hypothalamic or pituitary tumors, cranial irradiation, head trauma, pituitary infarction, and various types of CNS infections. In addition, psychosocial deprivation, hypothroidism, poorly controlled diabetes mellitus, treatment of precocious puberty with LH-releasing hormone agonists, and pharmacologic agents such as glucocorticoids, methylphenidate, and dextroamphetamine may induce transient GH insufficiency.

Short stature also occurs with several conditions that are not associated with a true GH deficiency or insufficiency. These conditions include intrauterine growth restriction; constitutional growth delay; malnutrition; malabsorption of nutrients associated with inflammatory bowel disease, celiac disease, and cystic fibrosis; chronic renal failure; skeletal and cartilage dysplasia; and genetic syndromes such as Turner syndrome. In addition, many children are diagnosed with idiopathic or normal variant short stature. These patients have heights that are significantly lower than the third percentile but present with normal GH serum concentrations and no specific underlying explanation for short stature.

Children with GHD short stature usually are born with an average birth weight. Decreases in growth velocity generally become evident between the ages of 6 months and 3 years. In contrast, GH insufficiency may arise at any age during growth and development. The clinical characteristics of GHD or GH-insufficient children are listed in Table 86–3.

Several factors must be considered in the diagnosis of GH deficiency or insufficiency. Standard epidemiologic growth charts developed by the National Center for Health Statistics typically are used to determine the percentile of anthropometric measurements, such as height, weight, and head circumference. Pubertal stage typically is determined using the Tanner method. Bone age is determined according to published standards, and growth velocity is calculated to determine the patient’s height velocity percentile using standard growth-velocity charts. GH deficiency is rarely seen in the absence of delayed skeletal maturation and decreased growth velocity. In addition, several different provocative stimuli that induce GH secretion may be used diagnostically to determine GH status. Common provocative pharmacologic GH stimuli include insulin-induced hypoglycemia, clonidine, L-dopa, arginine, glucagon, and GHRH. A subnormal GH response during childhood is arbitrarily defined as a peak GH serum concentration <10 mcg/L during a 2-hour period after administration of one of these agents. How, ever, this maximum may be lower, depending on the specific assay and GH reference product used. For prepubertal and early pubertal patients (Tanner stage less than III), priming with sex hormones may improve the specificity of GH provocation tests. Some patients exhibit clinical signs of GH deficiency, subnormal growth velocity, and delayed bone age despite GH levels that are within normal limits after provocative testing. This makes diagnosis in this group of patients very difficult. Diagnosis based on GH stimulation tests becomes further complicated because of the paucity of data reporting the normal range of GH concentrations after provocative testing in healthy children and the fact that commercial GH and IGF-1 assays currently available may not be equivalent. Although a gold standard for diagnosis of GH deficiency does not exist, treatment is generally recommended for children who have “idiopathic short stature” and pass GH provocative testing but have most of the following criteria: height greater than 2.25 standard deviations below the mean for age; subnormal growth velocity; delayed bone age; low serum IGF-1 and/or insulin-like growth factor binding protein 3 (IGFBP-3); and other clinical features consistent with GH deficiency. Ultimately, careful consideration of multiple factors by a pediatric endocrinology specialist is required to correctly diagnose GH deficiency. Of note, more than half of children diagnosed with GH deficiency are found to secrete normal quantities of GH and IGF-1 in adulthood.

**TREATMENT**

**Growth Hormone Deficiency**

**PHARMACOLOGIC THERAPY**

The treatment of GH deficiency with pituitary-derived human GH was first reported in the late 1950s. The National Hormone and Pituitary Program was founded by the National Institutes of Health in 1963 to coordinate the collection of human pituitary glands and purification of GH for administration to children with GH deficiency. In 1985, three deaths linked to Creutzfeldt-Jakob disease (CJD) were identified in young individuals who were previously treated with human pituitary GH. An evaluation of National Hormone and Pituitary Program data identified 26 cases of fatal CJD in a cohort of 6,107 patients who received treatment with human pituitary-derived GH in the United States between 1963 and 1985. Human pituitary GH was withdrawn from the U.S. market because of the strong likelihood that the CJD was transmitted through contaminated human pituitary-derived GH. Shortly after the withdrawal of human pituitary GH, the U.S. Food and Drug Administration (FDA) approved the first recombinant DNA-derived GH for treatment of GH insufficiency. Prior to the introduction of recombinant GH, the number of individuals who received treatment for GH insufficiency was relatively small because of the limited availability of human pituitary tissue for GH extraction. Currently, with the widespread availability of recombinant GH products, a large number of children can receive GH replacement therapy at higher doses.
Most pediatric endocrinologists in the United States believe that GH therapy is appropriate treatment in certain patients with non-GHD short stature. However, given the high cost of therapy and small increases in height, use of GH in this patient population remains controversial.

**RECOMBINANT GROWTH HORMONE**

Recombinant GH is currently considered the mainstay of therapy for treatment of GHD short stature. GH replacement therapy in children with documented GHD short stature produces a significant improvement in growth velocity within the first year of therapy and significantly improves final adult height. The initial increase in growth velocity often is referred to as catch-up growth. Most of the initial studies evaluating the efficacy of GH therapy in GHD children were conducted for short periods of time in small numbers of patients, and, until recently, information about the long-term outcome of GH therapy was limited. Initial data suggested that final adult height is not substantially improved, with an average final adult height reported to be two standard deviations below the population mean. Although these results were disappointing, it is important to note that a substantial percentage of patients included in these studies initially had received human pituitary GH in relatively low doses because of its limited availability. In addition, current GH dosing regimens with regard to frequency of administration have changed, making these data difficult to interpret and apply to patients who are receiving GH replacement therapy today. Recent studies evaluating the adult height of children who received only recombinant GH therapy with currently recommended dosing regimens suggest that current recombinant GH therapy has a greater impact on final adult height than previously reported.

These studies have reported average final adult heights ranging from 0.5 to 1.7 standard deviations below the population mean. Initiation of therapy at an early chronologic age, prior to the onset of puberty, is associated with a more favorable increase in final height. Therefore, prompt diagnosis of GH deficiency and early initiation of replacement therapy with recombinant GH are crucial factors in optimizing the final adult height of children with GH deficiency.

Recombinant GH has been shown to increase the short-term growth rate in pediatric patients with chronic renal insufficiency, Turner syndrome, idiopathic short stature, Prader-Willi syndrome, short stature homeobox gene (SHOX) deficiency, Noonan syndrome, and children born small for gestational age (SGA), and is approved by the FDA for treatment of growth failure associated with these conditions. GH is also FDA approved for treatment of adult GH deficiency, short bowel syndrome in patients receiving specialized nutritional support, and acquired immunodeficiency syndrome wasting syndrome. When used in adult patients, the recommended dosage of recombinant GH is significantly lower than the dosage used in pediatric patients. Adult patients with GH deficiency during childhood must have the diagnosis of GH deficiency confirmed when they are adults. Long-term GH therapy in GHD adults significantly decreases body fat, increases muscle mass, and improves exercise capacity. GH therapy in adults has been shown to improve the cardiac risk profile, bone mineral density, and psychological well-being. In addition, GH is being investigated for a variety of disorders, including infertility, chronic fatigue, obesity, and natural aging. Use of GH as an anabolic agent for management of acute catabolism is not recommended.

The majority of short children in the United States do not have an identifiable medical cause for their condition, but with widespread availability of several recombinant GH formulations, many children have received GH therapy regardless of the underlying etiology of their short stature. The use of recombinant GH therapy in children with non-GHD short stature, also referred to as idiopathic short stature, has been studied by many investigators and was approved by the FDA in 2003. However, the use of GH therapy in this patient population remains controversial. A meta-analysis of 38 clinical studies evaluating the efficacy of GH treatment in children with idiopathic short stature reported average increases in final adult height of 4 to 5 cm (1.6–2 inches) following a mean duration of therapy of 4.7 years. This corresponded to an increase above the predicted final adult height of 0.56 to 0.63 standard deviations of the population mean. A more recently published randomized, double-blind, placebo-controlled trial with a mean GH treatment duration of 4.4 years reported an increase in final adult height of 3.7 cm (1.5 inches). The slightly smaller height increase reported in the later study may be explained by the more stringent study design, lower mean GH doses, and GH treatment initiation at an older age (peripubertal) compared to the studies included in the meta-analysis.

Ten different recombinant GH products currently are available for use in the United States (Genotropin, Humatrope, Norditropin, Nutropin, Nutropin AQ, Omnitrope, Saizen, Serostim, Tev-Tropin, and Zorbtive) Each of these products contains somatropin. Somatropin is composed of the same amino acid sequence as human pituitary GH. Recombinant GH formulations must be administered by intramuscular or subcutaneous injection. Nutropin AQ, Norditropin, and omnitrope are the only GH products available as liquid formulations. The remaining products are formulated as lyophilized powders for injection, and patients must be instructed regarding proper administration. A needle-free injection device (Tject) is available for use with Tev-Tropin. This device delivers a thin stream of recombinant GH that penetrates the stratum corneum and deposits into the subcutaneous tissue. This product may be particularly useful for patients who experience significant adverse effects from injections. The potency of GH products is expressed as international units per milligram (international units/mg), with 1 mg containing approximately 2.6 international units of GH. Direct comparisons between the different recombinant GH products have not been published. However, all GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/week. Recombinant GH can be administered daily or in equal doses 6 times per week, depending on the specific GH product used. Dosing regimens with greater frequency of administration have been shown to provide more favorable short-term growth responses. GH replacement therapy should be initiated as early as possible after diagnosis of GH insufficiency and continued until a desirable height is reached or growth velocity has decreased to <2.5 cm per year after the pubertal growth spurt. However, the suitable time point for discontinuation of therapy with growth-promoting doses remains controversial. Glucocorticoids may inhibit the growth-promoting effects of recombinant GH, and concomitant administration of androgens, estrogens, thyroid hormones, or anabolic steroids may accelerate epiphyseal closure and compromise final height.

Three large databases, the National Cooperative Growth Study, the Kabi International Growth Study, and the Australian and New Zealand growth database (OZGROW), have been developed to collect postmarketing adverse effect data or reports associated with recombinant GH. Development of these databases was prompted by the unexpected and tragic cases of CJD reported...
Endocrinologic Disorders

SECTION 8

hypothyroidism, or chronic treatment with pharmacologic doses of recombinant IGF-1 products are not intended for use in subjects with secondary IGF-1 deficiency (defined as children with height standard deviation score ≤−3.0, plus normal or elevated GH concentration) or GH standard deviation score ≤−3.0 plus basal IGF-1 standard deviation score ≤−3.0 plus normal or elevated GH concentration). Additional adverse effects experienced by patients receiving recombinant IGF-1 products include injection-site reactions, tonsillar/adenoidal hypertrophy, lymphoid hypertrophy, coarsening facial features, anaphylaxis, headache, dizziness, and arthralgia. Intracranial hypertension has been reported in a small number of patients. Additional studies are needed to elucidate the exact role of recombinant IGF-1 products in the management of short stature not caused by GH gene deletion or GH receptor defects.

## EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate monitoring of therapy for GHD and non-GHD short stature includes regular assessments of height, weight, growth velocity, serum alkaline phosphatase, and bone age every 6 to 12 months. Additional laboratory tests to monitor for potential adverse effects include serum glucose concentration and thyroid function. The dose of GH will periodically need to be increased as weight increases in growing children.

## PHARMACOECONOMIC CONSIDERATIONS

The treatment of short stature with recombinant GH is expensive. Despite the prohibitive cost, recombinant GH remains the mainstay of therapy for children with GHD short stature. However, treatment of non-GHD short stature with recombinant GH is not widely accepted. The benefits in final adult height and increases in growth velocity, particularly in children with true GH deficiency, are associated with significant psychosocial benefits. Many clinicians believe that GH therapy can improve quality of life and should be made available to all children with short stature, regardless of whether or not they are GH deficient. Until studies using recombinant GH more definitively demonstrate improvements in both final adult height and quality of life, the cost-effectiveness of GH, particularly for non-GHD short stature, remains uncertain.

## CONCLUSIONS

GH deficiency during childhood results in short stature. Replacement with recombinant GH is considered the mainstay of therapy for patients with GHD short stature, but its use for treatment of non-GHD short stature remains controversial, albeit such treatment is FDA approved. Recombinant GH has proven to be safe for use in children and is associated with few adverse effects. The synthetic GHRH sermorelin and other GH-releasing peptides and preparations of IGF-1 may provide benefit for patients with non-GHD short stature. GH regimens can be particularly demanding and inconvenient for pediatric patients because they must be administered by subcutaneous injection. Knowledge of the long-term benefits and risks is critical to the development of rational, cost-effective treatments for patients with short stature.

### RECOMBINANT INSULIN-LIKE GROWTH FACTOR-1

Recombinant IGF-1 products, consisting of either IGF-1 alone (mecasermin [Increlex]) or IGF-1 in combination with IGFBP-3 (mecasermin rinfabate [Iplex]), have been recently approved by the FDA for the treatment of children with short stature due to severe primary IGF-1 deficiency (defined as children with height standard deviation score ≤−3.0 plus basal IGF-1 standard deviation score ≤−3.0, plus normal or elevated GH concentration) or GH gene deletion with neutralizing antibodies to GH. Recombinant IGF-1 products are not intended for use in subjects with secondary forms of IGF-1 deficiency, such as GH deficiency, malnutrition, hypothyroidism, or chronic treatment with pharmacologic doses of antiinflammatory steroids. Recombinant IGF-1 products have been shown to increase growth velocity in children with short stature who have low IGF-1 serum concentrations and resistance to GH. However, the efficacy of these agents is less than that reported with GH products in patients with GH deficiency.

The recommended dose of mecasermin is 0.04 to 0.12 mg/kg administered by subcutaneous injection twice daily. Mecasermin rinfabate is administered by once-daily injections at a dose of 1 to 2 mg/kg. Because of the insulin-like effects of these products, patients should be monitored very closely for hypoglycemia, and the drug should be initiated at a dose at the lower end of the dosage range and administered with a meal or snack. The incidence of hypoglycemia may be less frequent with mecasermin rinfabate because of the longer half-life of the combination product. Additional adverse effects experienced by patients receiving recombinant IGF-1 products include injection-site reactions, tonsillar/adenoidal hypertrophy, lymphoid hypertrophy, coarsening facial features, anaphylaxis, headache, dizziness, and arthralgia. Intracranial hypertension has been reported in a small number of patients. Additional studies are needed to elucidate the exact role of recombinant IGF-1 products in the management of short stature not caused by GH gene deletion or GH receptor defects.
PROLACTIN

PHYSIOLOGIC EFFECTS

Prolactin is secreted in a pulsatile fashion by the lactotroph cells of the anterior pituitary, with the highest peak concentrations observed during sleep. The secretion of prolactin is regulated primarily by tonic hypothalamic inhibitory effects of dopamine. As described earlier in this chapter and as listed in Table 86–1, many factors can affect prolactin secretion. During pregnancy, prolactin serum concentrations rise substantially above normal. All other conditions characterized by excess prolactin serum concentrations, known as hyperprolactinemia, are considered pathologic.

HYPERPROLACTINEMIA

Hyperprolactinemia is a state of persistent serum prolactin elevation. Prolactin concentrations >20 mcg/L in women, and >25 mcg/L in men, observed on multiple occasions are generally considered indicative of hyperprolactinemia. Hyperprolactinemia usually affects women of reproductive age. The incidence of hyperprolactinemia in the general population is reported to be <1%. Hyperprolactinemia has several etiologies. The most common causes are benign prolactin-secreting pituitary tumors, known as prolactinomas, and various medications. Prolactinomas are classified according to size. Prolactin-secreting microadenomas are <10 mm in diameter and often do not increase in size. In contrast, macroadenomas are tumors with a diameter >10 mm that continue to grow and can cause invasion of surrounding tissues.

In the presence of a prolactinoma, prolactin serum concentrations may remain normal or may be markedly elevated to thousands of micrograms per liter. Any pharmacologic agent that antagonizes dopamine or increases the release of prolactin can induce hyperprolactinemia (Table 86–4). Serotonin is a strong stimulator of prolactin secretion, and selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, paroxetine, sertraline, and fluvoxamine are the medications most frequently associated with hyperprolactinemia. Prior to the increased use of SSRIs, antipsychotic medications with potent dopamine-receptor blockade, such as the phenothiazine derivatives and haloperidol, were most often identified as the cause of drug-induced hyperprolactinemia. Metoclopramide and domperidone, an antiemetic available in Europe, are potent dopamine-receptor antagonists reported to induce hyperprolactinemia. Although the exact mechanism of action remains to be determined, the calcium channel-blocking agent verapamil has been associated with cases of hyperprolactinemia. Methyldopa and reserpine, although not used frequently in clinical practice today, are antihypertensive agents that can stimulate prolactin secretion. Prolactin concentrations may increase with administration of GnRH analogs such as leuprolide or goserelin. Other medications rarely reported to cause hyperprolactinemia include H2-receptor blocking agents, benzodiazepines, tricyclic antidepressants, dexfenfluramine, opioids, protease inhibitors, and monoamine oxidase inhibitors. Prolactin levels do not typically rise to >150 mcg/L in cases of drug-induced hyperprolactinemia. Measurement of serum prolactin concentrations prior to the initiation of therapy with medications known to cause prolactin elevation may obviate the need for extensive examination of pituitary function and aid with the appropriate diagnosis of drug-induced hyperprolactinemia.

Less common etiologies include CNS lesions that physically compress the pituitary stalk and interrupt tonic hypothalamic dopamine secretion, resulting in hyperprolactinemia. Increased TRH concentrations in hypothyroidism can stimulate prolactin secretion and cause hyperprolactinemia. During conditions of renal or hepatic compromise, the clearance of prolactin is decreased, resulting in elevated prolactin concentrations. Despite vigorous diagnostic effort, the cause of hyperprolactinemia cannot always be determined. This is known as idiopathic hyperprolactinemia and most likely is a result of the presence of very small tumors that are not detected by standard imaging techniques. It should be noted that many physiologic factors, such as stress (including the stress of phlebotomy), sleep, exercise, coitus, and eating, also can induce transiently elevated prolactin levels. This emphasizes the importance of obtaining multiple prolactin measurements to confirm the diagnosis. Ideally, after an intravenous line is placed in the patient’s arm, the patient should rest in a supine position or in a chair for 2 hours before prolactin samples are collected.

Elevated prolactin serum concentrations inhibit gonadotropin secretion and sex-steroid synthesis. Because prolactin concentrations >60 mcg/L are associated with anovulation, women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea and infertility. In addition, approximately 40% to 80% of women with hyperprolactinemia will have galactorrhea. The clinical presentation of patients with hyperprolactinemia is summarized in Table 86–5.

The diagnosis of hyperprolactinemia, as defined by multiple prolactin serum concentrations >20 mcg/L in women and >25 mcg/L in men, is relatively simple. However, identifying the underlying cause of this abnormality may be more challenging. Patients with modest prolactin elevations should have multiple prolactin serum determinations to minimize the potential for detecting only transient increases in prolactin. A careful medication history is essential, and the presence of hypothyroidism, renal failure, or hepatic dysfunction should be evaluated. If the cause of hyperprolactinemia remains ambiguous, a computed tomography scan or magnetic resonance imaging study should be performed to determine the presence of a pituitary tumor. If an underlying cause of elevated prolactin serum concentration is not determined, the hyperprolactinemia is considered to be idiopathic.

### Clinical Presentation of Hyperprolactinemia

**General**
- Hyperprolactinemia most commonly affects women and is very rare in men.

**Signs and symptoms**
- The patient may complain of symptoms related to local effects of the prolactin-secreting tumor, such as headache and visual disturbances, that result from tumor compression of the optic chiasm.
- Female patients experience oligomenorrhea, amenorrhea, galactorrhea, infertility, decreased libido, hirsutism, and acne.
- Male patients experience decreased libido, erectile dysfunction, infertility, reduced muscle mass, galactorrhea, and gynecomastia.

**Laboratory tests**
- Prolanin serum concentrations at rest will be >20 mcg/L on multiple occasions.

#### TREATMENT

**Hyperprolactinemia**

The treatment of hyperprolactinemia depends on the underlying cause of the abnormality. In cases of drug-induced hyperprolactinemia, discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations. In cases for which an appropriate therapeutic alternative does not exist, medical therapy with dopamine agonists is warranted. Sex-steroid replacement also should be considered. Treatment options for the management of prolactinomas include clinical observation, medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgical removal of the tumor. Because prolactin-secreting microadenomas are very small and typically do not increase in size, treatment of these tumors is primarily directed toward alleviating symptoms. The goal of therapy is to normalize prolactin serum concentrations and reestablish gonadotropin secretion to restore fertility and reduce the risk of osteoporosis. In patients with asymptomatic elevations in serum prolactin, observation and close follow up are appropriate. For women with amenorrhea who do not wish to become pregnant, dopamine agonist therapy may not be necessary. In these patients, sex steroid replacement and close follow up may be sufficient. Treatment goals are more aggressive in patients with prolactin-secreting macroadenomas because these tumors are larger and can cause invasion of local tissues with significant visual defects. Therefore, in addition to normalizing prolactin concentrations, tumor shrinkage and correction of visual defects are primary goals of treatment.

Medical therapy with dopamine agonists usually is more effective than transsphenoidal surgery for both types of pituitary prolactinomas. Postsurgical cure rates differ depending on tumor type and expertise of the neurosurgeon. Long-term cure rates are reported to be approximately 60% for microprolactinomas and only 25% for macroprolactinomas. Transsphenoidal surgery for removal of prolactinomas usually is reserved for patients who are refractory to or cannot tolerate therapy with dopamine agonists and for patients with very large tumors that cause severe compression of adjacent tissues. Radiation therapy may require several years for effective tumor shrinkage and reduction in serum prolactin concentrations and usually is used only in conjunction with surgery.

**PHARMACOLOGIC THERAPY**

Medical therapy with dopamine agonists has proven to be very effective in normalizing prolactin serum concentrations, restoring menstruation, and reducing tumor size in approximately 80% to 90% of patients with microprolactinomas over 3 to 6 months of therapy. Bromocriptine has been the mainstay of therapy since the 1970s. Cabergoline is a long-acting dopamine agonist that offers the advantage of less-frequent dosing. In recent years cabergoline has replaced bromocriptine as the agent of choice for the medical management of prolactinomas.

**BROMOCRIPTINE**

Bromocriptine was the first D2-receptor agonist to be used in the treatment of hyperprolactinemia and has been the mainstay of therapy for over 20 years. It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration, with maximal suppression occurring after 8 hours and suppressive effects persisting for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 90% of patients with microprolactinomas and 70% of patients with macroprolactinomas.

For the management of hyperprolactinemia, bromocriptine therapy typically is initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects. The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg/day, although some patients may require doses as high as 40 mg/day. Bromocriptine usually is administered in two or three divided doses, but once-daily dosing has also been shown to be effective.

The most common adverse effects associated with bromocriptine therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, and diarrhea also are common. Bromocriptine should be administered with food to decrease the incidence of adverse gastrointestinal effects. Although most of these adverse effects diminish with continued treatment, approximately 12% of patients will not tolerate the adverse effects associated with bromocriptine therapy. Vaginal preparations of bromocriptine have been studied in an effort to decrease the incidence of adverse effects associated with oral dosage forms.

Because most patients with hyperprolactinemia are women with a principal complaint of infertility, the safety of bromocriptine in pregnancy must be considered. One report of 100 pregnancies in women who received bromocriptine throughout gestation did not detect an increase in the risk for spontaneous abortion or incidence of congenital anomalies. Although bromocriptine does not appear to be teratogenic, most clinicians discontinue therapy as soon as pregnancy is detected because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown. In patients with macroprolactinomas undergoing rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy.

**PERGOLIDE**

Pergolide is a dopamine-receptor agonist with affinity for both D2- and D3-receptors. This agent is 10 to 1,000 times more potent than bromocriptine on a per milligram basis. In the United States, pergolide was never FDA approved for treatment.

**BROMOCRIPTINE**

Bromocriptine was the first D2-receptor agonist to be used in the treatment of hyperprolactinemia and has been the mainstay of therapy for over 20 years. It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration, with maximal suppression occurring after 8 hours and suppressive effects persisting for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 90% of patients with microprolactinomas and 70% of patients with macroprolactinomas.

For the management of hyperprolactinemia, bromocriptine therapy typically is initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects. The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg/day, although some patients may require doses as high as 40 mg/day.

Bromocriptine usually is administered in two or three divided doses, but once-daily dosing has also been shown to be effective.

The most common adverse effects associated with bromocriptine therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, and diarrhea also are common. Bromocriptine should be administered with food to decrease the incidence of adverse gastrointestinal effects. Although most of these adverse effects diminish with continued treatment, approximately 12% of patients will not tolerate the adverse effects associated with bromocriptine therapy.

Vaginal preparations of bromocriptine have been studied in an effort to decrease the incidence of adverse effects associated with oral dosage forms.

Because most patients with hyperprolactinemia are women with a principal complaint of infertility, the safety of bromocriptine in pregnancy must be considered. One report of 100 pregnancies in women who received bromocriptine throughout gestation did not detect an increase in the risk for spontaneous abortion or incidence of congenital anomalies. Although bromocriptine does not appear to be teratogenic, most clinicians discontinue therapy as soon as pregnancy is detected because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown. In patients with macroprolactinomas undergoing rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy.

**PERGOLIDE**

Pergolide is a dopamine-receptor agonist with affinity for both D2- and D3-receptors. This agent is 10 to 1,000 times more potent than bromocriptine on a per milligram basis. In the United States, pergolide was never FDA approved for treatment.
of hyperprolactinemia. However, it was used for many years as an effective alternative to bromocriptine in the management of patients with hyperprolactinemia and offered the advantage of once-daily dosing. 

In 2007, pergolide was withdrawn from the U.S. market because of cases of cardiac valvulopathy. Pathologic assessment suggested that the valvulopathy associated with pergolide appeared to be similar to that reported with other ergot alkaloids.

### CABERGOLINE

Cabergoline is a long-acting dopamine agonist with high selectivity and affinity for dopamine D₂-receptors. This agent is approved for treatment of hyperprolactinemia and has been shown to effectively reduce serum prolactin concentrations in 80% to 90% of hyperprolactinemic patients. Cabergoline also effectively reduces tumor size in patients with both microprolactinomas and macroadenomas. 

In a multicenter randomized trial comparing the efficacy of cabergoline and bromocriptine, serum prolactin levels were normalized in 83% of patients receiving cabergoline and 58% of patients receiving bromocriptine after 6 months of therapy. 

Cabergoline also has proved effective in patients who are intolerant of or resistant to bromocriptine, and data suggest that cabergoline is as effective in men as in women with microprolactinomas and macroadenomas.

Cabergoline is commercially available as 0.5-mg oral tablets. The initial dose of cabergoline for treatment of hyperprolactinemia is 0.5 mg once weekly or in divided doses twice weekly. This dose may be increased by 0.5-mg increments at 4-week intervals based on serum prolactin concentrations. The usual dose is 1 to 2 mg weekly; doses >3 mg per week are infrequently required. However, doses as high as 12 mg weekly have been used safely in patients with treatment-resistant prolactinomas. Following oral administration, peak serum concentrations are obtained within 2 hours, and food does not affect absorption. Data from animal studies indicate that cabergoline is widely distributed to well-perfused organs, including the pituitary gland. The elimination of cabergoline from the pituitary appears to be very slow; this rate may explain the long duration of action. Cabergoline is extensively metabolized in the liver by hydrolysis, and the dose should be reduced in patients with severe hepatic failure. This drug is eliminated primarily in the feces, and the elimination half-life ranges from 79 to 155 hours in hyperprolactinemic patients.

The most common adverse effects reported with use of cabergoline are nausea, vomiting, headache, and dizziness. These effects are similar to the adverse effects reported with bromocriptine and pergolide. However, in a large comparative study evaluating bromocriptine and cabergoline, fewer patients receiving cabergoline reported adverse effects than did patients receiving bromocriptine, and only 3% of the patients in the cabergoline group withdrew from the study because of adverse effects versus 12% of patients taking bromocriptine. Other adverse events associated with use of cabergoline include gastrointestinal complaints, drowsiness, fatigue, paresthesias, dyspnea, suffocation sensation, and epistaxis. As with other dopamine agonists, adverse events usually occur early in therapy and subside with continued treatment. However, in one study 15% to 20% of patients receiving cabergoline experienced a recurrence of early symptoms or an onset of new symptoms after several weeks of treatment. Mild-to-moderate decreases in blood pressure have been observed in up to 50% of patients taking cabergoline; however, the incidence of symptomatic orthostatic hypotension has not been significant. Transient increases in serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in small numbers of patients receiving cabergoline. Pleuropulmonary disease and newly diagnosed cardiac valve regurgitation have been reported with cabergoline use at the larger doses used in the treatment of Parkinson’s disease. Although symptomatic cardiac valve abnormalities have not been observed with cabergoline when administered in doses used for the treatment of prolactinomas, some clinicians have recommended routine echocardiography for patients receiving long-term cabergoline treatment for prolactinomas.

Use of cabergoline in pregnancy has not been extensively studied. However, several case reports of women who received cabergoline therapy during the first and second trimesters of pregnancy have not documented an increased risk of spontaneous abortion, congenital abnormalities, or tubal pregnancy. However, prospective data in large numbers of pregnancies are lacking. Because of the long half-life and limited data on cabergoline use in pregnancy, current guidelines recommend that women receiving cabergoline therapy who plan to become pregnant should discontinue the medication as soon as pregnancy is detected.

Other dopamine agonists that have been used in the treatment of hyperprolactinemia but are not commercially available in the United States include lisuride, terguride, metergoline, dihydroergocristine, and quinagolide. Quinagolide, a D₂-receptor agonist used frequently in Europe, is dosed once daily. Quinagolide has been shown to be as effective as bromocriptine for the management of hyperprolactinemia and may be effective in the treatment of patients who are resistant to or intolerant of bromocriptine.

### EVALUATION OF THERAPEUTIC OUTCOMES

Prolactin serum concentrations should be monitored every 3 to 4 weeks after the initiation of any dopamine-agonist therapy to assess efficacy and appropriately titrate medication dosage. In addition, symptoms such as headache, visual disturbances, menstrual cycles in women, and sexual function in men should be evaluated to assess clinical response to therapy. Once prolactin concentrations have normalized and clinical symptoms of hyperprolactinemia have resolved with dopamine-agonist therapy, prolactin serum concentrations should be monitored every 6 to 12 months. In patients receiving long-term treatment, the dose of the dopamine agonist can be gradually reduced or discontinued in some patients. For patients with macroprolactinomas who have normal serum prolactin concentrations and at least a 50% reduction in tumor size, medical therapy may be withdrawn every 2 to 5 years to assess if remission has been achieved. In the case of macroprolactinomas, the dose of the dopamine agonist can be gradually reduced in some cases, but complete drug discontinuation should be attempted only if careful monitoring for renewed tumor growth can be ensured.

### PHARMACOECONOMIC CONSIDERATIONS

Medical therapy with dopamine agonists is more effective than transsphenoidal surgery or radiation for the management of hyperprolactinemia. Because most patients receive therapy for long periods, the medical management of hyperprolactinemia may result in considerable cost. Cabergoline has been shown to be more effective than bromocriptine and offers additional advantages such as a decreased incidence of adverse effects and improved patient compliance. Most clinicians agree that cabergoline is the most efficacious dopamine agonist currently available. However, the cost of cabergoline therapy is approximately 2 times greater than that of bromocriptine. Pharmacoeconomic studies are needed to assess whether the higher cost of cabergoline therapy is balanced by the potential added benefits.
CONCLUSIONS

Hyperprolactinemia is a common disorder that can have a significant impact on fertility. Hyperprolactinemia is most commonly caused by the presence of prolactin-secreting pituitary tumors and various medications that antagonize dopamine or increase the secretion of prolactin. Available treatment options for this disorder include medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgery. In most cases, medical therapy with dopamine agonists is considered the most effective treatment. Cabergoline has replaced bromocriptine as the mainstay of medical therapy because it appears to be better tolerated and more effective. However, because of limited data regarding the safety of cabergoline during pregnancy, bromocriptine remains the preferred agent when fertility is the primary purpose for treatment.

PANHYPOPITUITARISM

Panhypopituitarism is a condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary hormone deficiencies. Patients with panhypopituitarism may have ACTH deficiency, gonadotropin deficiency, GH deficiency, hypothyroidism, and hyperprolactinemia. Panhypopituitarism can be classified as either primary or secondary depending on the etiology. Primary panhypopituitarism involves an abnormality within the secretory cells of the pituitary, whereas secondary panhypopituitarism is caused by a lack of proper external stimulation needed for normal release of pituitary hormones. Some of the most common causes of panhypopituitarism include primary pituitary tumors, ischemic necrosis of the pituitary, surgical trauma, irradiation, and various types of CNS infections. Pharmacologic treatment of panhypopituitarism is essential and consists of replacement of specific pituitary hormones after careful assessment of individual deficiencies. Replacement most often consists of glucocorticoids, thyroid hormone preparations, and sex steroids. Administration of recombinant GH also may be necessary. Patients with panhypopituitarism will need lifelong replacement therapy and constant monitoring of multiple homeostatic functions.

ABBREVIATIONS

ACTH: adrenocorticotropic hormone
CJD: Creutzfeldt-Jakob disease
CRH: corticotropin-releasing hormone
FSH: follicle-stimulating hormone
GH: growth hormone
GHD: growth hormone deficient
GHRH: growth hormone-releasing hormone
GnRH: gonadotropin-releasing hormone
IGF: insulin-like growth factor
IGFBP-3: insulin-like growth factor 1 binding protein 3
LH: luteinizing hormone
OGTT: oral glucose tolerance test
SGA: small for gestational age
SHOX: short stature homeobox-containing gene
SSRI: selective serotonin reuptake inhibitor
TRH: thyrotropin-releasing hormone
TSH: thyroid-stimulating hormone
VIP: vasoactive intestinal peptide

REFERENCES

Physiologic changes modify drug pharmacokinetics during pregnancy, including changes in absorption, protein binding, distribution, and elimination, requiring individualized drug selection and dosing.

Although drug-induced teratogenicity is a serious concern during pregnancy, most drugs required by pregnant women can be used safely. Informed selection of drug therapy is essential.

Healthcare practitioners must know where to find and how to evaluate evidence related to the safety of drugs used during pregnancy and lactation.

Pregnancy-influenced health issues, such as constipation, gastroesophageal reflux disease, and nausea/vomiting, can be treated safely and effectively with nonpharmacologic treatment or carefully selected drug therapy. Some acute and chronic illnesses pose additional risks during pregnancy, requiring treatment with appropriately selected and monitored drug therapies to avoid harm to the woman and the fetus.

Understanding the physiology of lactation and pharmacokinetic factors affecting drug distribution, metabolism, and elimination can assist the clinician in selecting safe and effective medications during lactation.

Drugs used in pregnancy and lactation is a topic often underemphasized in the education of health professionals. Drug use in pregnancy and lactation is a controversial and emotionally charged area because of medicolegal and ethical implications.

Clinicians are responsible for ensuring safe and effective therapy before conception, during pregnancy and parturition, and after delivery. Active patient participation is essential. Optimal treatments of illnesses during pregnancy sometimes differ from those used in the nonpregnant patient. Principles of drug use during lactation, although similar, are not the same as those applicable during pregnancy.

In many cases, medication dosing recommendations for acute or chronic illnesses in pregnant women are the same as for the general population. However, some cases require different dosing and selection of medications.

**PHYSIOLOGY OF PREGNANCY**

Fertilization and progression of pregnancy are complex, resulting in survival of only approximately 50% of embryos. Because most losses occur early, usually in the first 2 weeks after fertilization, many women don’t realize they were pregnant. Spontaneous loss of pregnancy later in gestation occurs in about 15% of pregnancies that survive the first 2 weeks after fertilization.

Fertilization occurs when a sperm attaches to a receptor on the outer protein layer of the egg, the zona pellucida, and renders the egg nonresponsive to other sperm. The attached sperm releases enzymes that cause the egg’s chromosomes to mature, allowing the sperm to fully penetrate the zona pellucida and contact the egg’s cell membrane. The membranes of the sperm and egg then combine to create a new, single cell called a zygote. Male and female chromosomes join in the zygote, fuse to create a single nucleus, and organize for cell division.

Fertilization usually occurs in the fallopian tube. The fertilized egg travels down the fallopian tube over 2 days, with cell division taking place. By day 3, the fertilized egg reaches the uterus. Cell division continues for another 2 to 3 days in the uterine cavity before implantation. Approximately 6 days after fertilization, the cell mass is termed a blastocyst. Human chorionic gonadotropin (hCG) now is produced in amounts detectable by commercial laboratories. Implantation begins with the blastocyst sloughing the zona pellucida to rest directly on the endometrium allowing initiation of growth into the endometrial wall. By day 10 postfertilization, the blastocyst is implanted under the endometrial surface and receives nutrition from maternal blood. Now it is called an embryo.
After the embryonic period (between weeks 2 and 8 postfertilization), the conceptus is renamed a fetus. Most body structures are formed during the embryonic period, and they continue to grow and mature during the fetal period. The fetal period continues until the pregnancy reaches term, approximately 40 weeks after the last menstrual period.6

**Gravidity** is the number of times that a woman is pregnant.5,7 A multiple birth is counted as a single pregnancy. **Parity** refers to the number of pregnancies exceeding 20 weeks' gestation and relates information regarding the outcome of each pregnancy. In sequence, the numbers reflect (1) term deliveries, (2) premature deliveries, (3) aborted and/or ectopic pregnancies, and (4) number of living children. A woman who has been pregnant four times; has experienced two term deliveries, one premature delivery, and one ectopic pregnancy; and has three living children would be designated G4P2156.

**PREGNANCY DATING**

Pregnancy lasts approximately 280 days (about 40 weeks or 9 months); the time period is measured from the first day of the last menstrual period to birth.5,7 **Gestational age** refers to the age of the embryo or fetus beginning with the first day of the last menstrual period, which is about 2 weeks prior to fertilization. When calculating the estimated due date, add 7 days to the first day of the last menstrual period then subtract 3 months. Pregnancy is divided into three periods of 3 calendar months, each called a trimester.

**PREGNANCY SIGNS AND SYMPTOMS**

Early symptoms of pregnancy include fatigue and increased frequency of urination. At approximately 6 weeks' gestation, nausea and vomiting can occur. While commonly called **morning sickness**, it can happen at any time of the day. Nausea and vomiting usually resolve at 12 to 18 weeks' gestation. A pregnant woman can feel fetal movement in the lower abdomen at 16 to 20 weeks of gestation. Signs of pregnancy include cessation of menses, change in cervi
cal mucus consistency, bluish discoloration of the vaginal mucosa, increased skin pigmentation, and anatomic breast changes.5,7

**MATERNAL PHARMACOKINETIC CHANGES IN PREGNANCY**

1 Normal physiologic changes that occur during pregnancy may alter medication effects, resulting in the need to more closely monitor and, sometimes, adjust therapy. Physiologic changes begin in the first trimester and peak during the second trimester. For medications that can be monitored by blood or serum concentration measurements, monitoring should occur throughout pregnancy.

During pregnancy, maternal plasma volume, cardiac output, and glomerular filtration increase by 30% to 50% or higher, potentially lowering the concentration of renally cleared drugs.8,9 As body fat increases during pregnancy, the volume of distribution of fat-soluble drugs may increase. Plasma albumin concentration decreases, which increases the volume of distribution of drugs that are highly protein bound. However, unbound drugs are more rapidly cleared by the liver and kidney during pregnancy, resulting in little change in concentration. Nausea and vomiting, as well as delayed gastric emptying, may alter the absorption of drugs. Likewise, a pregnancy-induced increase in gastric pH may affect the absorption of weak acids and bases. Higher levels of estrogen and progesterone alter liver enzyme activity and increase the elimination of some drugs but result in accumulation of others.

**TRANSPLACENTAL DRUG TRANSFER**

Although once thought to be a barrier to drug transfer, the placenta is the organ of exchange for a number of substances, including drugs, between the mother and fetus. Most drugs move from the maternal circulation to the fetal circulation by diffusion.10 Certain chemical properties, such as lipid solubility, electrical charge, molecular weight, and degree of protein binding of medications, may influence the rate of transfer across the placenta.10

Drugs with molecular weights less than 500 Da readily cross the placenta, whereas larger molecules (600–1,000 Da) cross more slowly.10 Drugs with molecular weights greater than 1,000 Da, such as insulin and heparin, do not cross the placenta in significant amounts.10 Lipophilic drugs, such as opiates and antibiotics, cross the placenta more easily than do water-soluble drugs.10 Maternal plasma albumin progressively decreases while fetal albumin increases during the course of pregnancy, which may result in higher concentrations of certain protein-bound drugs in the fetus.10 Fetal pH is slightly more acidic than maternal pH, permitting weak bases to more easily cross the placenta. Once in the fetal circulation, the molecule becomes more ionized and less likely to diffuse back into the maternal circulation.10

**DRUG SELECTION DURING PREGNANCY**

2 Although some drugs have the potential to cause teratogenic effects, most medications required by pregnant women can be used safely. There are many misconceptions about the association of medications and birth defects.

The baseline risk for congenital malformations is approximately 3% to 6%, with approximately 3% considered severe. Medication exposure is estimated to account for less than 1% of all birth defects.2 Genetic causes are responsible for 15% to 25%, other environmental issues (e.g., maternal conditions and infections) account for 10%, and the remaining 65% to 75% of congenital malformations result from unknown causes.2

Factors such as the stage of pregnancy during exposure, route of administration, and dose, can affect outcomes.2,11 In the first 2 weeks following conception, exposure to a teratogen may result in an "all-or-nothing" effect, which could either destroy the embryo or cause no problems.11 During organogenesis (18 to 60 days postconception), organ systems are developing, and teratogenic exposures may result in structural anomalies. For the remainder of the pregnancy, exposure to teratogens may result in growth retardation, central nervous system abnormalities, or death.2 Examples of medications associated with teratogenic effects in the period of organogenesis include chemotherapy drugs (e.g., methotrexate, cyclophosphamide), sex hormones (e.g., diethylstilbestrol), lithium, retinoids, thalidomide, certain antiepileptic drugs, and coumarin derivatives. Other medications such as nonsteroidal antiinflammatory drugs and tetracycline derivatives are more likely to exhibit effects in the second or third trimester.

In summary, a small number of medications have the potential to cause congenital malformations, and many can be avoided during pregnancy. In situations where a drug may be teratogenic but is necessary for maternal care, considerations related to route of administration and dosing may lessen the risk.

**METHODS OF DETERMINING DRUG SAFETY IN PREGNANCY**

3 When assessing the safety of using medications during pregnancy, an important consideration for the clinician is how to evaluate the quality of the evidence. Ideally, safety data from randomized, controlled trials is most desirable, but pregnant women are not usually eligible for participation in clinical trials. Other types of data commonly used to estimate the risk associated with medication use during pregnancy are animal studies, case reports, case-control
studies, prospective cohort studies, historical cohort studies, and voluntary reporting systems.

Animal studies are a required component of drug testing, but extrapolation of the results to humans is not always valid. Thalidomide was found to be safe in some animal models but proved to have teratogenic effects in human offspring.

Case reports are usually of limited value because a birth defect in the infant of a woman who used a medication during pregnancy may have occurred by chance. Case-control studies identify an outcome (congenital anomaly), match subjects with and without that outcome, and report how often exposure to a suspected agent occurred. Recall bias is a concern in case-control studies, as women with an affected pregnancy may be more likely to remember drugs used during the pregnancy than those who had a normal outcome.

Cohort studies evaluate the intervention (use of a particular drug) in a group of persons and compare outcomes in a similar group of subjects without the intervention. Prospective studies eliminate some of the problems with recall bias but require time and large numbers of participants. Despite these disadvantages, cohort studies are often used for evaluating the effects of a drug exposure on pregnancy outcomes.

Teratology information services provide pregnant women with information about potential exposures during pregnancy and follow these women throughout the pregnancy to assess the outcomes of the pregnancy. The services may publish pooled data to facilitate information sharing about medications used during pregnancy. Some pharmaceutical companies have organized voluntary reporting systems (also called pregnancy registries) for drugs used during pregnancy.

RESOURCES

1. Computerized databases (e.g., www.motherisk.org, LactMed [www.toxnet.nlm.nih.gov]), tertiary compendia, and textbooks with information from large cohorts of treated women offer valuable assistance. New information regarding drug use in pregnancy and lactation can be obtained from searches of the primary literature for cohort and case-control studies.

The Food and Drug Administration (FDA) developed risk categories (i.e., A, B, C, D, X, with A considered safe and X considered teratogenic) to guide clinicians regarding medication risk during pregnancy. The FDA ranks very few as safe during pregnancy (category A) because a controlled trial is required to establish safety; this implies that few drugs are safe. Because of multiple limitations of the risk categories, the FDA proposed a new system in 2008 to replace the risk categories with a fetal risk summary and lactation risk summary. Each section discusses clinical considerations and summarizes available data.

In summary, drug safety information from product labeling may provide a rough estimate of risks for medication-related adverse fetal outcomes but must be used in conjunction with other information sources to make decisions about medication use in pregnant women.

GENERAL RECOMMENDATIONS FOR OPTIMIZING USE OF MEDICATIONS IN PREGNANCY

2. Medications are necessary during pregnancy for treatment of acute and chronic conditions. Identifying patterns of medication use before conception, eliminating nonessential medications and discouraging self-medications, minimizing exposure to medications known to be harmful, and adjusting medication doses are all strategies to optimize the health of the mother while minimizing the risk to the fetus.

PRECONCEPTION PLANNING

Pregnancy outcomes are influenced by maternal health status, lifestyle, and history prior to conception. More than 60% of pregnancies in the United States are unintended. Of women who receive prenatal care, 18% seek it after the first trimester. The goal of preconception care is health promotion, evidence-based screening, and intervention in all women of reproductive age to ensure optimal health and improve pregnancy outcomes.

The most common major congenital abnormalities are neural tube defects (NTDs), cleft palate and lip, and cardiac anomalies. Each year in the United States approximately 1 in 1,000 infants are born with NTDs. Folic acid supplementation substantially reduces the incidence in offspring of women, including those with a history of NTDs. Neural tube defects occur within the first month of conception because neural tube closure occurs during the first month of pregnancy. Folic acid supplementation is recommended throughout a woman’s reproductive years since many pregnancies are unplanned and may not be recognized until after the first month. Dietary intake of folic acid is not sufficient. For all women of childbearing age, folic acid supplementation with 400 mcg/day is recommended. For women at high risk or those who have a history of NTDs, folic acid 4 mg/day is recommended. Multivitamins should not be used to achieve folic acid doses higher than contained in the multivitamin product because of risk for vitamin A toxicity.

Use of alcohol and recreational drugs during pregnancy is associated with birth defects. Of births in the United States in 2003, 10% of mothers smoked tobacco during pregnancy. Smoking can cause preterm birth, low birth weight, and other adverse outcomes. In a systematic review of 72 trials of smoking cessation and perinatal outcomes, incidences of low birth weight and preterm birth were reduced, and birth weight increased by 54 g with smoking cessation. Cognitive behavioral therapy and nicotine replacement therapy resulted in similar rates of smoking cessation; however, offering incentives and social support resulted in the highest rate of success. For women who cannot stop smoking with behavioral interventions alone, nicotine replacement therapies can be used with behavioral therapy. Use of nicotine replacement during pregnancy is controversial since its use is not supported by clinical trial data; however, nicotine replacement theoretically imparts less risk than exposure to the over 4,000 chemicals found in cigarettes. Intermittent delivery formulations are recommended because most users ingest a smaller total daily dose than received from the topically applied patch. If patches are necessary because of poor tolerability of other agents, they should be applied for 16 rather than 24 hours per day. The initial dose of the patch should be similar or higher than that used for nonpregnant women because of nicotine’s rapid metabolism during pregnancy. Bupropion is an alternative to nicotine replacement for women who have not quit smoking with behavioral therapy because the risk of its use appears to be less than that of cigarette smoking. However, its efficacy for smoking cessation in pregnancy has not been determined. Bupropion use during pregnancy should be reported to the GlaxoSmithKline pregnancy registry. Varenicline’s safety and effectiveness during pregnancy are unknown.

Prevention of infectious disease during pregnancy is important. Vaccination against Rubella and hepatitis B as part of preconception care reduces adverse pregnancy outcomes. Influenza vaccination is generally offered to women who will be in their second or third trimester during influenza season. Women with comorbid conditions that increase risks of complications from influenza should receive vaccine regardless of time of gestation.
PREGNANCY-INDUCED ISSUES

Pregnancy causes or exacerbates conditions that pregnant women commonly experience, including constipation, gastroesophageal reflux, hemorrhoids, and nausea and vomiting. Gestational diabetes, gestational hypertension, and venous thromboembolism have the potential to cause adverse pregnancy consequences. Gestational thyrotoxicosis is usually self-limiting.

GASTROINTESTINAL TRACT

The prevalence of constipation during pregnancy ranges from 25% to 40%. Light physical exercise and increased intake of dietary fiber and fluid should be instituted first.21 If additional treatment is needed, supplemental fiber and/or a stool softener is appropriate.25 Osmotic laxatives (polyethylene glycol, lactulose, sorbitol, and magnesium and sodium salts) are acceptable treatments but should be reserved for occasional use only. Polyethylene glycol is considered by some the ideal laxative for use in pregnancy.25,22 Senna and bisacodyl can be used occasionally. Castor oil and mineral oil should be avoided.

Gastroesophageal reflux disease occurs in up to 80% of pregnant women.21 An algorithm starting with lifestyle and dietary modifications (e.g., small, frequent meals; alcohol and tobacco avoidance; food avoidance before bedtime; elevation of the head of the bed) should be used. If symptoms are not relieved, use of antacids (aluminum, calcium, or magnesium preparations) or sucralfate is acceptable. Sodium bicarbonate and magnesium trisilicate should be avoided. Evidence supports the use of ranitidine and cimetidine. Literature evaluating the use of famotidine and nizatidine is limited, but they are likely safe. If a patient is unresponsive to lifestyle changes and histamine-2 receptor blockers, metoclopramide is a viable option. Relatively few data are available on the use of proton pump inhibitors during pregnancy; use should be reserved for women with complicated or intractable gastroesophageal reflux.

The prevalence of hemorrhoids during pregnancy is believed to be higher than in the general population.21 Therapy during pregnancy is conservative (i.e., high intake of dietary fiber, adequate oral fluid intake, and use of sitz baths) and may be helpful; however, there is a paucity of supporting data for all management options. Topical anesthetics, skin protectants, and astringents can be used. Other options for refractory hemorrhoids include rubber band ligation, sclerotherapy, and surgery.

Nausea and vomiting affect up to 90% of pregnant women, usually beginning during the fifth week of gestation and lasting through the first trimester; however, about 15% of women experience it throughout pregnancy.21,24 Hyperemesis gravidarum (HEG; i.e., unrelenting vomiting causing weight loss of more than 5% prepregnancy weight and ketonuria) occurs in about 1% to 3% of women.24 Dietary modifications, such as eating frequent, small, bland meals and avoiding fatty foods, may be helpful. Applying pressure at acupuncture point P6 on the volar aspect of the wrist may be beneficial.

A number of pharmacotherapeutic approaches have been tried for treatment of nausea and vomiting. Multivitamins, pyridoxine (vitamin B6), and antihistamines (including doxylamine) have shown efficacy.21,24 Phenothiazines and metoclopramide are widely used and generally considered safe.21,24 Evidence of safety and efficacy with ondansetron is limited, but ondansetron can be considered for HEG when other treatments fail. Corticosteroids are effective for HEG but are associated with a small increase in the risk of oral clefts when used during the first trimester.21,24 Ginger has shown efficacy for hyperemesis in randomized, controlled trials and is probably safe.21,24

GESTATIONAL DIABETES

Gestational diabetes mellitus (GDM) is glucose intolerance first identified during pregnancy. It develops in about 4% of pregnant women, although the prevalence may range from 1% to 14%.25 Screening for gestational diabetes is controversial.25-27 The U.S. Preventative Services Task Force Independent Expert Panel concluded that there is a lack of evidence proving that screening for gestational diabetes decreases adverse maternal and fetal outcomes.27 However, the American Diabetes Association recommends glucose testing for women with risk factors of gestational diabetes (e.g., obesity, history of the condition, glycosuria, or strong family history of diabetes) at the first prenatal visit.25 If normal, testing should be repeated between weeks 24 and 28 of gestation. Pregnant women considered to have average risk should undergo testing for GDM between weeks 24 and 28 of gestation unless they are considered low risk. To meet criteria for low risk, a woman must fulfill all the following: (a) age younger than 25 years, (b) normal body weight, (c) no known diabetes in first-degree relatives, (d) no history of abnormal glucose tolerance, (e) no history of adverse obstetric outcomes, and (f) not a member of an ethnic group with a high prevalence of GDM (e.g., African Americans, Native Americans, Asian Americans, Hispanic Americans, Pacific Islanders). Initial screening for hyperglycemia in pregnancy is similar to that in the general population and is described in the American Diabetes Association practice guidelines.25

Dietary modification is considered first-line therapy for all women who have GDM, with additional caloric restriction for obese women.26,28 Daily self-monitoring of blood glucose is required. Insulin therapy with recombinant human insulin should be initiated if the following levels are not achieved with dietary modification: fasting plasma glucose concentrations below 90–99 mg/dL (5.0–5.5 mmol/L), 1-hour postprandial plasma glucose concentration less than or equal to 140 mg/dL (7.8 mmol/L), or 2-hour postprandial plasma glucose concentration below 120–127 mg/dL (6.7–7.0 mmol/L).29 Glyburide is an alternative because it minimally crosses the placenta.26,28 Metformin may also be an alternative, but it crosses the placenta and is less well studied than insulin or glyburide.29 There are data, though limited, supporting the use of postprandial over preprandial blood glucose monitoring in women requiring insulin treatment.29 Recommended targets for self-monitored blood glucose are preprandial plasma glucose concentration between 80 and 110 mg/dL (4.4–6.1 mmol/L) and 2-hour postprandial plasma glucose concentration below 155 mg/dL (8.6 mmol/L).30

Evidence supporting dietary modification, self-monitored blood glucose, exercise, and pharmacologic interventions for women with GDM is largely based on one randomized clinical trial that showed reductions in perinatal morbidity (composite of death, nerve palsy, bone fracture, and shoulder dystocia) with nutritional education, blood glucose monitoring, and insulin treatment.31,32

HYPERTENSION

Approximately 10% of pregnancies are complicated by hypertension at some time during the pregnancy. Hypertension in pregnancy is divided into four categories: chronic hypertension (preexisting hypertension), gestational hypertension (hypertension without proteinuria), preeclampsia (hypertension with proteinuria), and preeclampsia superimposed on chronic hypertension.33,34 Treatment of mild-to-moderate hypertension (defined as systolic blood pressure 140–169 mm Hg or diastolic blood pressure 90–109 mm Hg) reduces the risk of severe hypertension by 50%, but does not substantially affect fetal outcomes. However, severe hypertension (blood pressure greater than or equal to 160–170 mm Hg
systolic or 110 mm Hg diastolic) can cause maternal complications, hospital admission, and potential premature delivery. Preeclampsia complicates 2%–8% of pregnancies and can cause poorer outcomes, including eclampsia (seizures in addition to preeclampsia), renal failure, coagulopathy, preterm delivery, and intrauterine growth restriction.33

Supplemental calcium 1–2 g/day decreases the relative risk of hypertension by 30% (range 14%–43%) and preeclampsia by 48% (range 31%–67%).33 High-risk patients (those with the lowest initial calcium intake) benefited most; however, even women with adequate calcium intake at baseline had a 38% decrease in risk of preeclampsia. Therefore, 1 g/day of supplemental calcium is recommended for all pregnant women.

Nondrug managements center on activity restriction, psychosocial therapy, and biofeedback; however, no evidence indicates that any of these approaches improves pregnancy outcome, and prolonged bed rest may increase the risk of venous thromboembolic disease. Studies of antihypertensive drug therapy for mild-to-moderate hypertension (less than or equal to 160/110 mm Hg) in pregnancy have not conclusively shown a decrease in the risk of preeclampsia, neonatal death, preterm birth, or small-for-gestational-age babies. However, antihypertensives do prevent severe hypertension.34,35 No evidence supports selection of one pharmacologic agent as first-line therapy. Commonly used drugs include methyldopa, labetalol, and calcium channel blockers.36 Agents affecting the renin-angiotensin pathway (i.e., angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists, and renin inhibitors) should probably be avoided throughout pregnancy.36

Drug therapy is indicated for women with blood pressure greater than or equal to 160/110 mm Hg. However, no consensus exists on when to initiate treatment, and recommendations vary from at least 140/90 mm Hg to 160/105 mm Hg.36 As with mild-to-moderate hypertension in pregnancy, conclusive evidence supporting one antihypertensive agent over another is lacking, although agents to avoid include magnesium sulfate (unless indicated for eclampsia prevention), high-dose diazoxide, nimodipine, and chlorpromazine.37

Low-dose aspirin (75–81 mg/day) started after 12 weeks’ gestation in women at risk for preeclampsia decreases the risk of its development by 17%, which corresponds to prevention of one preeclampsia case for every 72 at-risk women treated.35,38 Low-dose aspirin also results in decreased rates of preterm birth (8% reduction) and fetal or neonatal death (14% reduction). In high-risk women (i.e., previous severe preeclampsia, renal disease, autoimmune disease, diabetes, and chronic hypertension), use of low-dose aspirin prevents one case for every 19 women treated. Features associated with moderate risk for preeclampsia include first pregnancy, adolescent maternal age, mild increase in blood pressure without proteinuria, abnormal uterine artery Doppler scan, family history of severe preeclampsia, and multiple fetuses; although some evidence refutes young maternal age as a risk factor.33,38

Preeclampsia may progress rapidly to eclampsia, a medical emergency, so signs and symptoms of preeclampsia must be monitored carefully. Eclampsia is the occurrence of seizures superimposed on preeclampsia.33,39 Signs and symptoms of preeclampsia include blood pressure elevation; proteinuria; persistent severe headache; persistent new epigastric pain; visual changes; vomiting; hyper-reflexia; sudden and severe swelling of hands, face, or feet; low platelet count; hemolytic anemia; increased serum creatinine; and elevated liver enzyme tests. The only cure for preeclampsia is delivery of the fetus. Treatment of hypertension in women with preeclampsia is the same as mentioned previously (e.g., methyldopa, labetalol, calcium channel blockers). Magnesium sulfate is recommended to prevent eclampsia as well as treat eclamptic seizures. Diazepam and phenytoin should be avoided.

**THYROID ABNORMALITIES**

During pregnancy, stimulation of the thyroid gland may occur because of hCG’s structural similarity to serum TSH (thyrotropin).40 In women with HEG, gestational transient thyrotoxicosis may result. Women are usually asymptomatic but may present with vomiting, increased serum free thyroxine, and decreased thyrotropin. Gestational transient thyrotoxicosis resolves as concentrations of hCG decline toward the end of the first trimester. Treatment with antithyroid medications is not usually needed. Nausea and vomiting can be treated as for patients without this pseudohypothyroid state.

Postpartum thyroiditis occurs in approximately 4% of women within 1 to 4 months after childbirth because of increased thyroid hormone secretion.41 Most cases resolve spontaneously; however, β-blockers (propranolol or labetalol) can provide symptomatic relief of adrenergic symptoms. Patients should be monitored since 2% to 5% of women go on to develop transient hypothyroidism 4 to 8 months postpartum; levothyroxine replacement is suggested for a total of 6 to 12 months. Up to 30% of women develop permanent hypothyroidism.

**THROMBOEMBOLISM**

Venous thromboembolism is estimated to occur in 0.06% to 0.13% of pregnancies; a five- to tenfold increase in risk over nonpregnant women.42

- Unfractionated heparin or adjusted-dose low-molecular weight heparin are recommended for treatment of acute thromboembolism during pregnancy, although low-molecular-weight heparin is preferred.32 Treatment should be continued throughout pregnancy and for 6 weeks after delivery. Warfarin is not used because it causes nasal hypoplasia, stippled epiphyses, limb hypoplasia, and eye abnormalities; the risk period appears to be between 6 and 12 weeks’ gestation. However, central nervous system anomalies are associated with second- and third-trimester exposure. Antepartum monitoring or anticoagulation plus postpartum anticoagulation is recommended for women with a single episode of thromboembolism and either (a) thrombophilia, (b) an idiopathic cause without thrombophilia, or (c) a pregnancy- or estrogen-related risk factor. Antepartum and postpartum anticoagulation should be given to women with two or more episodes of thromboembolism, women with antithrombin III deficiency, and women receiving long-term anticoagulation. Pregnant women with antiphospholipid antibodies and a history of pregnancy complications should receive antepartum aspirin in addition to unfractionated heparin or low-molecular-weight heparin.

Women with prosthetic heart valves should receive low-molecular-weight heparin or unfractionated heparin during pregnancy.43 After a discussion of potential risks, a heparin product can be used until week 13 of gestation with subsequent substitution of warfarin until the middle of the third trimester when a heparin product should again be used. High-risk women with prosthetic heart valves (e.g., older-generation mitral valve, history of thromboembolism) may also receive low-dose aspirin (75–100 mg/day).

**CONCLUSION**

Women with pregnancy-influenced gastrointestinal issues can be treated safely with lifestyle modification or medications, many of them nonprescription. Gestational diabetes, hypertension, and thyrotoxicosis may or may not require drug therapy. Venous thromboembolism treatment or prevention usually requires therapy with a low-molecular-weight heparin or unfractionated heparin.
**ACUTE CARE ISSUES IN PREGNANCY**

In some cases, the risks associated with the acute illness are magnified during pregnancy, and early screening and treatment become critical. In other cases, such as during treatment of certain sexually transmitted diseases, the urgency regarding treatment comes from an increased likelihood of infection leading to preterm labor. Occasionally, common acute care issues, such as migraine headache, improve during pregnancy.

**URINARY TRACT INFECTION**

The most common infections in pregnant and nonpregnant women are urinary tract infections. The incidence of asymptomatic bacteriuria ranges from 2% to 10% while estimates for acute cystitis range from 1% to 4%. Untreated, bacteriuria progresses to pyelonephritis in 20% to 40% of pregnant women compared with 1% to 2% of nonpregnant women. Complications of pyelonephritis include premature delivery, low infant birth weight, hypertension, anemia, bacteremia, and transient renal failure. A urine culture is recommended to screen pregnant women for urinary tract infections between 12 and 16 weeks’ gestation. Use of other methods, such as dipsticks that measure nitrites or leukocyte esterase, requires high bacterial concentrations for a positive result, leading to false negatives and underdiagnosis.

*Escherichia coli* is the primary cause of infection in 80% to 90% of cases. Other gram-negative rods, such as *Proteus mirabilis* and *Klebsiella pneumoniae*, as well as Group B Streptococcus (GBS) account for some infections. The presence of GBS in the urine indicates heavy colonization of the genitourinary tract, increasing the risk for GBS infection in the newborn.

To decrease the risk of pyelonephritis and its complications, treatment of asymptomatic bacteriuria is necessary. β-Lactams are not known teratogens; however, the incidence of *E. coli* resistance to ampicillin and amoxicillin limits their use as single agents. Cephalexin is safe and effective. Nitrofurantoin is also safe and effective, but it is not active against *Proteus* species. It should not be used after week 37 in patients with glucose-6-phosphate dehydrogenase deficiency because of a theoretical risk for hemolytic anemia in the neonate; however, no cases are reported. Sulfa-containing drugs can contribute to the development of newborn kernicterus; use should be avoided during the last weeks of gestation. Trimethoprim is a folate antagonist and is relatively contraindicated during the first trimester because of associations with cardiovascular malformations. Regionally, increased rates of *E. coli* resistance to trimethoprim-sulfa may limit its use. Fluoroquinolones and tetracyclines are contraindicated. The optimal duration of therapy for asymptomatic bacteriuria in pregnancy has not been determined. Courses of 7 to 14 days are common, but shorter courses of 3 days may be sufficient. Repeat urine cultures are recommended monthly for the remainder of gestation if asymptomatic bacteriuria is diagnosed.

Signs and symptoms of acute cystitis include urgency, frequency, hematuria, pyuria, and dysuria. Treatment of acute cystitis is similar to that of asymptomatic bacteriuria. Using outcomes of cure rates, recurrent infection, incidence of preterm delivery or rupture of membranes, admission to neonatal intensive care, need for change of antibiotic, or incidence of prolonged fever, antibiotic treatment has demonstrated effectiveness in treating symptomatic urinary tract infections (including pyelonephritis) in pregnancy.

No specific treatment appeared superior to other commonly used treatments.

Patients with pyelonephritis usually present with bacteriuria and systemic symptoms of fever, flank pain, nausea, and vomiting. Hospitalization is the standard of care for pregnant women since many require intravenous hydration. Inpatient therapy has included parenteral administration of cephalosporins (e.g., cefazolin, ceftriaxone), ampicillin plus gentamicin, or ampicillin-sulbactam. Switching to oral antibiotics can occur after the woman is afebrile for 48 hours. Outpatient antibiotic therapy can be considered after initial inpatient observation in women who are afebrile and less than 24 weeks’ gestation. The total duration of antibiotic therapy for acute pyelonephritis is 10 to 14 days. Suppression therapy with nitrofurantoin 100 mg given nightly is recommended for the remainder of gestation because of the 20% recurrence rate.

**SEXUALLY TRANSMITTED DISEASES**

Sexually transmitted diseases in pregnant women range from infections that may be transmitted across the placenta and infect the infant prenatally (e.g., syphilis) to organisms that may be transmitted during birth and cause neonatal infection (e.g., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or herpes simplex virus) to infections that pose a threat for preterm labor (e.g., bacterial vaginosis). Screening is essential for early detection of most sexually transmitted diseases but may not be beneficial in other instances (e.g., bacterial vaginosis in low-risk patients). Sexual partners of women with certain infections (e.g., syphilis, *N. gonorrhoeae*, *C. trachomatis*) also require treatment to prevent recurrence of infection.

**Syphilis**

Serologic testing for syphilis should occur during the first prenatal visit. For women who live in areas with a high prevalence of syphilis, are at high risk, have not been previously tested, or had positive serology in the first trimester, additional serologic testing during the third trimester and at delivery is recommended. With the exception of neurosyphilis, which is treated with aqueous penicillin G, the drug of choice for all stages of syphilis is benzathine penicillin G. Penicillin effectively prevents transmission to the fetus and treats the fetus, if already infected. For pregnant women, the dose and route of administration are determined by the stage of syphilis and do not differ from recommendations for nonpregnant patients. No alternatives for penicillin are acceptable for penicillin-allergic pregnant women; therefore, penicillin skin testing and desensitization are required.

Treatment during the second half of pregnancy may increase the risk for preterm labor and fetal distress because a Jarisch-Herxheimer reaction may occur; however, treatment should not be withheld or delayed. All women should have serologic titers repeated at 28 to 32 weeks’ gestation, at delivery, and as dictated by recommendations for the stage of disease.

**Neisseria gonorrhoeae**

Perinatal gonococcal infection results from exposure to the infected cervix during birth. Symptoms usually manifest within 2 to 5 days after delivery. Milder manifestations include rhinitis, vaginitis, urethritis, and infection at the site of fetal monitoring. More severe presentations include ophthalmitia neonatorum and sepsis. Coinfection with *C. trachomatis* is common; treatment of most *N. gonorrhoeae* infections includes treatment for *C. trachomatis*. Cotreatment regimens for presumptive or diagnosed *C. trachomatis* infection are described in the following section. Ceftriaxone 125 mg intramuscularly as a single dose or cefixime 400 mg orally in a single dose is the treatment of choice for *N. gonorrhoeae* cervical infection. Women with a cephalosporin allergy or intolerance should receive a single dose of spectinomycin 2 g intramuscularly. Quinolones and tetracyclines are contraindicated.
TABLE 87-1 | Recommended Regimens for Treatment of Cervical Infections Due to Chlamydia in Pregnancy

| First-line treatment | \( \text{Azithromycin 1 g orally in a single dose or} \) Amoxicillin 500 mg orally three times daily for 7 days |
| Alternative regimens | \( \text{Erythromycin base 500 mg orally four times per day for 7 days or} \) Erythromycin base 250 mg orally four times per day for 14 days |
| | \( \text{Erythromycin ethylsuccinate 800 mg orally four times per day for 7 days or} \) Erythromycin ethylsuccinate 400 mg orally four times per day for 14 days |

Data from Centers for Disease Control and Prevention, Workowski KA, Berman SM Sexually transmitted diseases treatment guidelines, 2006. MMWR Recomm Rep 2006;55(RR-11):1–94.46

**Chlamydia trachomatis**

*Chlamydia trachomatis* infects the newborn through exposure to the infected cervix during delivery.46 Perinatal infection most commonly causes conjunctivitis that develops 5 to 12 days postpartum. A subacute, febrile pneumonia with an onset at ages 1 to 3 months may occur.

The treatment of choice for *C. trachomatis* cervicitis is azithromycin 1 g orally as a single dose or amoxicillin 500 mg three times daily for 7 days.46 Erythromycin base or ethylsuccinate regimens are alternatives, but gastrointestinal intolerance and the required frequency of administration may limit patient acceptance. Erythromycin estolate increases the risk for hepatotoxicity and should be avoided (Table 87–1).

**Genital Herpes**

Neonatal herpes often occurs in infants born to women lacking clinical evidence of genital herpes.46 The risk of neonatal transmission is under 1% for women with a history of recurrent herpes at term, but is 30% to 50% for women who initially acquire genital herpes during the first half of their pregnancy. However, because recurrent herpes is more common than initial episodes during pregnancy, it remains the cause for most cases of neonatal transmission.

Prevention strategies include counseling uninfected women to avoid intercourse during the third trimester with partners having known or suspected genital herpes infection.46,47 Women with no history of orolabial herpes should avoid receptive oral sex during the third trimester with partners who have orolabial herpes. Prevention of genital herpes transmission to pregnant women using antiviral agents has not been studied.

All women should be asked about symptoms of genital herpes at the time of delivery and should be examined for lesions.46,47 Women who have no symptoms (including prodromal symptoms) or lesions proceed with vaginal childbirth; however, those with evidence of an outbreak undergo cesarean section to decrease the risk of neonatal transmission.

Maternal use of acyclovir during the first trimester has not demonstrated an increased risk for birth defects.46 Valacyclovir is an alternative.47 Safety data with famciclovir are limited. For initial or recurrent episodes, most women receive oral acyclovir therapy while intravenous acyclovir is reserved for severe infections. Women with an initial outbreak late in pregnancy may receive acyclovir, cesarean section, or a combination of the two. Acyclovir use during the last month of pregnancy may reduce the frequency of cesarean section because of fewer recurrences. In women seropositive for herpes simplex virus but who have not experienced an outbreak, no data suggest a treatment benefit.

**Bacterial Vaginosis**

Bacterial vaginosis results from the lack of normal vaginal flora (i.e., *Lactobacillus* species) and replacement with anaerobic bacteria, mycoplasmas, and *Gardnerella vaginalis*.46 It is a risk factor for premature rupture of membranes, preterm labor, preterm birth, spontaneous abortion, and postpartum endometritis. Women with a history of preterm delivery should undergo screening for asymptomatic bacterial vaginosis at the first prenatal visit.

For symptomatic and asymptomatic women at high risk for preterm delivery, the recommended treatment regimen is metronidazole 500 mg orally twice daily for 7 days, metronidazole 250 mg orally three times daily for 7 days, or clindamycin 300 mg twice daily for 7 days. Conflicting data exist with regard to treating women at low risk for preterm labor. Vaginal preparations (e.g., metronidazole gel, clindamycin cream) have not demonstrated reductions in the risk of adverse pregnancy outcomes associated with bacterial vaginosis. Use of intravaginal clindamycin cream during the second half of pregnancy has caused low birth weight and neonatal infections.

**HEADACHE**

Primary headaches (e.g., tension, migraine) in pregnant women are the most common types of headache.48 Secondary headaches can also occur as a result of trauma, infection, preeclampsia, stroke, or cerebral venous thrombosis.

The majority of pregnant women with a history of migraine headaches experience symptom improvement during pregnancy. Eighteen percent to 86% of women improve, and the greatest improvements occur during the second and third trimesters.46,49 Improvement is more likely in women who have migraine without aura and less likely in women with a history of menstrual migraine. Women with menstrual migraine are more likely to have postpartum recurrence.

Relaxation, stress management, and biofeedback are all effective nonpharmacologic treatment methods.48,49 Acetaminophen (with or without codeine), codeine, or other narcotic analgesics can be used to treat headaches that do not respond to nonpharmacologic treatment. Aspirin should be avoided in the third trimester because it can cause narrowing of the ductus arteriosus, maternal and fetal bleeding, and decreased uterine contractility. Nonsteroidal antiinflammatory drugs (NSAIDs) are considered safe but are also contraindicated in the third trimester because of the potential for closure of the ductus arteriosus. Caffeine may be added to any of the foregoing treatments to improve response, but overuse may cause withdrawal headaches. Use of sumatriptan is controversial because of limited information about pregnancy outcomes with its use, but some clinicians recommend it for women with who have not responded to other agents.49 Ergotamine and dihydroergotamine are contraindicated. Metoclopramide can be used for patients who have migraine-associated nausea. Chronic, preventive treatment is reserved for women who have three to four severe episodes per month that are not responsive to other treatments. β-Blockers, such as propranolol, are commonly used but may be associated with side effects, including intrauterine growth retardation. Alternatives include calcium channel blockers and antidepressants.48,49

Tension headaches are less studied.48,49 Most women report no change in the frequency or intensity of tension headaches. Tension headaches may be difficult to distinguish from secondary headaches. Primary treatments for tension headache are nonpharmacologic interventions, including exercise, biofeedback, and massage. Simple analgesics such as acetaminophen, ibuprofen, or caffeine are used if nonpharmacologic treatments fail. Opioids are rarely used.48

**CHRONIC ILLNESSES IN PREGNANCY**

For the majority of women and their healthcare providers, pregnancy is a new consideration for a previously diagnosed health condition. Medications used to treat the chronic illness can often be used throughout the pregnancy and during breast-feeding.
ALLERGIC RHINITIS AND ASTHMA

Asthma and rhinitis are common chronic illnesses in pregnancy. During pregnancy, asthma control may change and worsen maternal oxygenation resulting in significant health consequences in the mother and fetus. Rhinitis itself is unlikely to cause harm to the mother or fetus but may be associated with diminished quality of life.

Asthma affects approximately 8% of pregnancies. During pregnancy almost equal proportions of patients have symptoms that worsen, improve, or remain unchanged. Health consequences of untreated or poorly treated asthma include preterm labor, pre-eclampsia, intrauterine growth restriction, premature birth, low birth weight, and stillbirth; therefore, the treatment goal is symptom control. Asthma is controlled when there are no daytime symptoms, limitations of activities, nocturnal symptoms, short-acting β2-agonist use, or exacerbations, and there is normal pulmonary function.

Caring for patients with asthma should include (a) assessment and monitoring (including measures of pulmonary function), (b) identifying and controlling exposure to allergens and irritants (e.g., tobacco smoke), (c) patient education, and (d) a stepped approach to medication use. The risks of medication use to the fetus are lower than the risks of untreated asthma.

Treatment recommendations are divided into six steps based on symptom control. A short-acting β2-agonist is recommended for all patients with asthma for quick relief of symptoms. For mild intermittent asthma, Step 1 recommends only a short-acting, inhaled β2-agonist; albuterol is preferred during pregnancy.

Initiation of treatment for persistent asthma should begin with Step 2 unless the patient has severely uncontrolled asthma, in which case treatment may start at Step 3. For persistent asthma, step-appropriate doses (low, medium, high) of inhaled corticosteroids form the foundation of the controller medication regimen. When possible, low-dose inhaled corticosteroids are the treatment of choice for women with mild persistent asthma. Budesonide is preferred during pregnancy, although other inhaled corticosteroids that were effective before pregnancy can be continued. Long-acting β2-agonists are considered safe to use during pregnancy because of the similar pharmacologic and safety profiles compared with short-acting agents; use should follow the stepwise approach.

Cromolyn, leukotriene receptor antagonists, and theophylline are considered alternative treatments but are not preferred because they are less effective (cromolyn), there is less experience with them (leukotriene receptor antagonists), and there is more potential toxicity (theophylline) than with inhaled corticosteroids. For patients with the most severe disease, addition of systemic corticosteroids is recommended to gain control of symptoms.

Allergic rhinitis may also improve, worsen, or remain the same during pregnancy. Treatment strategies include avoidance of allergens, immunotherapy, and pharmacotherapy. Immunotherapy is not contraindicated in pregnancy, but dose increases during pregnancy are not advised to lessen risk for anaphylaxis.

First-line medications to treat allergic rhinitis during pregnancy include intranasal corticosteroids, nasal cromolyn, and first-generation antihistamines (e.g., chlorpheniramine, hydroxyzine). Intranasal corticosteroids are the most effective treatment and have a low risk of systemic effect; beclomethasone and budesonide have been most widely studied. Second-generation antihistamines (i.e., loratadine and cetirizine) do not appear to increase fetal risk but are less extensively studied than first-generation products. Oral decongestants, such as pseudoephedrine, may be associated with an increased risk for the rare birth defect gastroschisis. Use of an external nasal dilator, short-term topical oxymetazoline, or inhaled corticosteroids may be preferable to use of oral decongestants, especially during early pregnancy.

DERMATOLOGIC CONDITIONS

Treatment of dermatologic conditions can often be delayed until after the delivery. If treatment is required during gestation, topical agents considered to have minimal pregnancy risk include bacitracin, benzoyl peroxide, ciclopirox, clindamycin, erythromycin, metronidazole, mupirocin, permethrin, and terbinafine. Topical corticosteroids are generally considered safe for use but should be applied at the lowest possible dose for the shortest time. Systemic agents considered safe include acyclovir, amoxicillin, azithromycin, cephalexin, ciprofloxacin, dicloxacillin, diphenhydramine, erythromycin (except estolate), nystatin, and penicillins. Lidocaine and lidocaine with epinephrine can be used topically during pregnancy. Acitretin, fluourouracil, isotretinoin, methotrexate, and thalidomide should be avoided because of teratogenic potential.

DIABETES

Poorly controlled diabetes can cause fetal malformations and fetal loss. Women with diabetes should use effective contraception until optimal glycemic control is achieved before attempting pregnancy. Additionally, diabetic retinopathy may worsen, hypertension may develop, and renal function may deteriorate during pregnancy, requiring enhanced monitoring for these target-organ problems.

For patients with both type 1 and type 2 diabetes, insulin is the drug treatment of choice. However, glyburide and metformin may be alternatives. Medical nutrition therapy and supervised physical activity programs should continue. Goals for self-monitored blood glucose are the same as for gestational diabetes.

EPILEPSY

Seizure frequency does not change for most pregnant women with epilepsy. Studies have demonstrated no frequency change in 54% to 80% of women with epilepsy, while decreased frequency ranges between 3% and 24% and increased frequency ranges from 14% to 32%. Seizures may become more frequent because of changes in maternal hormones, sleep deprivation, and medication adherence problems (because of perceived teratogenic risk). Another potential cause is changes in free serum concentrations of antiepileptic drugs resulting from increased maternal volume of distribution, decreased protein binding from hypoalbuminemia, increased hepatic drug metabolism, and increased renal drug clearance. A woman’s clinical condition and her free serum concentrations of antiepileptic drug should be the basis for dose adjustments.

The risks of untreated epilepsy to the fetus are considered to be greater than those associated with the antiepileptic drugs. Major malformations are two to three times more likely to occur in children born to women taking antiepileptic drugs than to those who do not. Major malformations with valproic acid are dose related and range from 6.2% to 10.7%; use of valproic acid should be avoided if possible during pregnancy to minimize the risk of NTDs (e.g., spina bifida), facial clefts, and cognitive teratogenicity. Rates of major malformation for monotherapy with antiepileptic drugs other than valproic acid range between 2.9% and 3.6%. Carbamazepine and lamotrigine appear to be safest based on available data. However, individual antiepileptic drugs are associated with malformations. Phenytoin, lamotrigine, and carbamazepine may cause cleft palate, while phenobarbital is associated with cardiac malformations. Polytherapy with antiepileptic drugs is associated with a greater rate of major malformation than monotherapy.

When possible, antiepileptic drug monotherapy is recommended with medication regimen optimization occurring before
conception. Medication change solely to minimize teratogenic risk is not recommended. If drug withdrawal is planned, it should be attempted at least 6 months before attempting to conceive. While vitamin K administration during the last month of gestation was previously recommended to decrease the risk of hemorrhagic complications in newborns, evidence to support this practice is lacking. The American Academy of Pediatrics recommends that all neonates receive vitamin K at delivery. All women taking antiepileptic drugs should receive folic acid supplementation; 4 to 5 mg starting before pregnancy and continuing through at least the first trimester.

**HUMAN IMMUNODEFICIENCY VIRUS INFECTION**

Pregnant women newly diagnosed with HIV, with or without prior treatment, should receive highly active antiretroviral therapy (HAART). The treatment regimen should be selected from those suggested for nonpregnant adults, with special consideration given to the teratogenic profile of each drug. Women currently receiving antiretroviral treatment should be continued on their regimen when possible. If antiretroviral drugs are being used exclusively to prevent mother-to-child transmission, prophylaxis may be delayed until after the first trimester.

Zidovudine is the mainstay of antiretroviral therapy and is recommended for use during pregnancy, labor, and delivery, as well as during the postpartum period. Lamivudine should be used along with zidovudine as the nucleoside reverse transcriptase inhibitor (NRTI) backbone of therapy when feasible. For HAART, two NRTIs plus either a nonnucleoside reverse transcriptase inhibitor (NNRTI) or a protease inhibitor is recommended; current guidelines recommend nevirapine or lamivudine/ritonavir. Efavirenz should be avoided during the first trimester and the entire pregnancy if possible. If therapy is discontinued during the first trimester, reintroduction of all medications should occur only when the ability to tolerate drug therapy is certain. All medications should be restarted at the same time to decrease risk of resistance. Zidovudine dosing recommendations during pregnancy are 300 mg twice daily or 200 mg three times a day. Intravenous zidovudine is recommended during labor, and the infant should receive the drug beginning 6 to 12 hours after birth and continuing for the first 6 weeks of life.

**HYPERTENSION**

Treatment of stage 1 or 2 chronic hypertension (blood pressure 140–179 mm Hg systolic or 90–109 mmHg diastolic) during pregnancy is controversial because the physiologic drop in blood pressure during the first half of pregnancy may result in improved blood pressure control without drug treatment. However, treatment may decrease uteroplacental blood flow and impair fetal development. Additionally, most of the increases in adverse fetal and maternal outcomes are caused by preeclampsia superimposed on chronic hypertension. Women should be monitored closely if treatment is discontinued, and therapy should be reinstated if blood pressure exceeds 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or if target-organ damage occurs. Alternatively, antihypertensive drugs may be continued (except for angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers) at the lowest effective dose. Use of diuretics (excluding spironolactone) is controversial but may be considered for chronic hypertension. Women with severe hypertension (blood pressure above 170 mmHg systolic or above 110 mmHg diastolic) should receive drug therapy to prevent occurrence of cerebrovascular hemorrhage or other target-organ damage. Available evidence does not support superior efficacy of one agent versus another for blood pressure reduction.

**MENTAL HEALTH CONDITIONS**

Psychiatric illness affects approximately 500,000 pregnancies each year. Anxiety disorders, including panic disorder, obsessive–compulsive disorder, generalized anxiety disorder, posttraumatic stress disorder, social anxiety disorder, and phobias, can cause adverse maternal and fetal outcomes such as spontaneous abortion, preterm delivery, prolonged labor, and fetal distress. Depression occurs in 10% to 16% of pregnant women. Maternal depression is associated with greater risk for premature birth, low birth weight, and fetal growth restriction. In addition to the potential impact of maternal depression on obstetric complications, untreated depression may have long-term implications for normal infant development. Up to 6.4% of Americans have bipolar disorder, with men and women equally affected, but the incidence in pregnancy is unknown. Patients with bipolar disorder may be more likely to relapse during pregnancy, especially with rapid discontinuation of drug therapy.

Schizophrenia occurs in 1% to 2% of women, however the incidence in pregnancy is unknown. Drug therapy is usually necessary, although some women refuse treatment because of concerns about teratogenicity or paranoid or delusional thinking. Maternal schizophrenia is associated with increased risk of perinatal death, low birth weight, small-for-gestational-age infants, cardiovascular malformations, preterm delivery, stillbirth, and infant death.

Nonpharmacologic therapies may be tried in pregnant women with psychiatric illnesses who fail to respond or inadequately respond to drug therapy and in those who refuse drug therapy. Cognitive behavioral therapy and interpersonal psychotherapy have been shown beneficial in the treatment of anxiety disorders and depression. Light therapy has also been effective for treatment of seasonal depression. Electroconvulsive therapy is considered safe and effective treatment of major depression, bipolar disorder, and schizophrenia.

Because most psychotropic medications are used to treat more than one condition, the reader should refer to other sources for information about treatment of specific mental health diagnoses. In general, monotherapy is preferred over polytherapy even if higher doses are required.

Neither the selective serotonin reuptake inhibitors (SSRIs) nor the tricyclic antidepressants are considered major teratogens. The SSRIs are the drugs of first choice for several mental health conditions in the general population and are widely used by pregnant women. Data suggest that paroxetine may cause a 1.5- to 2-fold increased risk of cardiac malformations; this finding has not been replicated for other SSRIs. About 1 two 2 newborns per 1,000 develop persistent pulmonary hypertension. Infants exposed to SSRIs in utero after 20 weeks’ gestation developed persistent pulmonary hypertension at a rate 6 times greater than the background rate; this finding needs further confirmation. Overall, the absolute risk of major malformations with SSRIs is small; approximately 2 in 1,000 births are affected. Use of SSRIs late in pregnancy can precipitate neonatal withdrawal symptoms consisting of irritability and difficulty with feeding and breathing. There are concerns about adverse effects in infants born to women who use SSRIs during pregnancy. However, women who stop taking antidepressants are more likely to relapse, and this can also have implications for the well-being of the infant.

Studies completed over 30 years ago showed an increased risk of oral clefts with diazepam use during pregnancy; these findings were not confirmed in a subsequent study. A recent meta-analysis found the absolute risk of oral cleft changed from 6 cases to 7 cases...
per 10,000 exposures (0.01%). Another large case-control study found no association between benzodiazepine use and congenital anomalies. Benzodiazepine use in the third trimester can cause infant sedation and withdrawal symptoms (i.e., restlessness, hypertension, hyperreflexia, tremulousness, apnea, diarrhea, vomiting). "Floppy baby syndrome," consisting of low Apgar scores, hypothermia, poor muscle tone, feeding difficulties, and poor temperature adaptation, has also been described.

Mood stabilizers, such as lithium, lamotrigine, carbamazepine, and valproic acid, are often used to treat bipolar disorder.65 The reader can find information related to the use of the seizure medications used for mood stabilization in the section on epilepsy.

Lithium’s place in the treatment of bipolar disorder is controversial because of concerns about cardiovascular anomalies, especially Ebstein anomaly, in exposed infants.64 A meta-analysis calculated that the relative risk for cardiac malformations was between 1.2 and 7.7 and for all congenital malformations was between 1.5 and 3. Stated differently, the risk for Ebstein anomaly after prenatal lithium exposure would rise from 1:20,000 to 1:1,000.64 Other reported neonatal side effects include floppy baby syndrome, nephrogenic diabetes insipidus, hypoglycemia, cardiac arrhythmias, thyroid dysfunction, polyhydramnios, and premature delivery.54–64 Lithium may cause lethargy, hypotonia, hypothermia, cyanosis, and changes in electrocardiogram in infants exposed through breast-feeding. If breastfeeding, the infant’s lithium levels, thyroid function, and complete blood count should be monitored.

Chlorpromazine, haloperidol, and perphenazine have long histories of use during pregnancy, with no reported significant teratogenic effect.65 Atypical antipsychotics are considered first-line treatment for schizophrenia because of their more favorable side-effect profiles and potential increased efficacy for treating negative symptoms compared with the older agents. However, use of atypical antipsychotics in pregnant women is controversial because of the limited data regarding teratogenic potential. Although olanzapine and clozapine have not been associated with increased risk for congenital malformations, they do cause weight gain and glucose intolerance, which have implications for poorer obstetric outcomes.66 One study found a higher rate (10% vs. 2%) of low-birth-weight infants with olanzapine, clozapine, quetiapine, and risperidone compared with nonexposed infants.66 At present, atypical antipsychotics do not appear to be safer than the typical agents.

THYROID DISORDERS

Hypothyroidism affects 0.1 to 0.3% of pregnancies.40 Untreated hypothyroidism increases the risk of preeclampsia, premature birth, miscarriage, and growth restriction; impaired neurological development in the fetus may also occur. Causes of hypothyroidism include autoimmune diseases (e.g., Hashimoto thyroiditis), iodine deficiency (uncommon in the United States), and thyroid dysfunction following surgery or ablative therapy for previous hyperthyroidism. Thyroid replacement therapy should be instituted with levothyroxine 0.1 to 0.15 mg/day in hypothyroid patients; the goal is to attain normal thyrotropin concentration. Women receiving thyroid replacement therapy before pregnancy may have an increased dosage requirement during pregnancy; any dose change should follow thyroid function testing. Laboratory follow-up of thyrotropin concentrations and free T should occur every 8 weeks.

Hyperthyroidism affects approximately 0.2% of pregnancies and is associated with fetal death, low birth weight, intrauterine growth restriction, and preeclampsia.49 Graves disease accounts for 95% of hyperthyroidism in pregnancy. Therapy includes the thiouamides (initial doses are propylthiouracil 100–150 mg or methimazole 5–20 mg). Either agent is given three times daily with dose reduction after becoming euthyroid. Surgery is reserved for the most severe cases. The risks of uncontrolled hyperthyroidism outweigh the risks of the thiouamides. Iodine-131 is contraindicated because of the risk of thyroid damage in the fetus. The goal of therapy is to attain free thyroxine concentrations near the upper limit of normal to allow for dose minimization and to limit fetal or neonatal hypothyroidism.

LABOR AND DELIVERY

Management of the pregnant woman during the perinatal period often requires drug therapy for pain and for potential complications.

PRETERM LABOR

Preterm labor occurs when there are cervical changes and uterine contractions between 20 and 37 weeks’ gestation.67,68 Preterm birth is the leading cause of infant morbidity and mortality in the United States, with an incidence of 12.8%. Risk factors for preterm delivery include previous preterm delivery, infections, multiple gestation, poverty, nonwhite race, maternal complication factors (e.g., smoking and use of illicit drugs or alcohol), and uterine functional causes (e.g., incompetent cervix); previous history and prior second trimester loss confer a higher risk.67,68

No adequate tests are available for monitoring and preventing preterm labor. Monitoring of uterine activity along with intensive surveillance does not minimize risk.68 The presence of fetal fibronectin, a glycoprotein found in cervicovaginal secretions, indicates a high risk of preterm birth. Cervical shortening is also associated with preterm delivery. Fetal fibronectin determinations and cervical ultrasound have not helped to prevent preterm labor but have been useful for their negative predictive value.68

Tocolytic Therapy

The purposes of tocolytic therapy are threefold: (a) postpone delivery long enough to allow for the maximum effect of antenatal steroid administration; (b) allow for transportation of the mother to a facility equipped to deal with high-risk deliveries; and (c) prolongation of pregnancy when there are underlying, self-limited conditions that can cause labor, such as pyelonephritis or abdominal surgery, that are unlikely to cause recurrent preterm labor.68–70

Tocolytics have not reduced the number of premature deliveries. The criteria for starting tocolysis are regular uterine contractions with cervical change. Tocolytic therapy should not be used in cases of intrauterine fetal demise, a lethal fetal anomaly, intrauterine infection, fetal distress, severe preeclampsia, vaginal bleeding, or maternal hemodynamic instability.

Four classes of tocolytics are available in the United States: β-agonists, magnesium, calcium channel blockers, and NSAIDs.71 All four therapies have similar effectiveness in prolonging pregnancy from 48 hours to 1 week. However, this prolongation of pregnancy was not associated with a statistically significant reduction in overall rates of respiratory distress syndrome or neonatal death.

The β-agonists terbutaline and ritodrine have been used for tocolytic therapy.72 Ritodrine is no longer available in the United States. Relative to other agents, β-agonists have a higher incidence of maternal side effects, including hyperkalemia, arrhythmias, hyperglycemia, hypotension, and pulmonary edema. Recommended terbutaline doses range from 250 to 500 mcg subcutaneously every 3 to 4 hours.70

Intravenous magnesium sulfate has been used for tocolysis; however, a Cochrane review does not support its effectiveness.72 Heterogeneity of study designs and results along with small treatment arms in included studies may partially explain this finding.
however, its use remains controversial.69 The incidence of cerebral palsy is increased in premature infants. In one study, intravenous magnesium use (6 g load followed by 2 g per hour continuous infusion) decreased the occurrence of moderate or severe cerebral palsy.71 Although not the primary end point, the study suggests that women at risk for imminent delivery (up to 34 weeks’ gestation) should receive intravenous magnesium. Maternal side effects are rare but can include pulmonary edema. At toxic levels, hypotension, muscle paralysis, tetany, cardiac arrest, and respiratory depression may occur.70 Magnesium undergoes renal excretion; dose adjustment is required in women with impaired renal function.

CURRENT CONTROVERSY

Intravenous magnesium sulfate is commonly used in the United States for tocolysis. Some advocate cessation of its use because a Cochrane review found no difference in preterm delivery in the 48 hours after administration and an increase in perinatal death.69,72

Nifedipine is associated with fewer side effects than magnesium or β-agonist therapy.69 Several studies have suggested that calcium channel blockers are superior to β-agonists for prolonging labor. One concern with the use of nifedipine is its hypotensive effect and corresponding change in uteroplacental blood flow. However, a meta-analysis showed reduced neonatal morbidity with calcium channel blocker use. With the initial diagnosis of preterm labor, 5 to 10 mg nifedipine can be administered sublingually every 15 to 20 minutes for three doses. After patient stabilization, if no evidence of continuing cervical dilation is seen, 10 to 20 mg nifedipine can be administered orally every 4 to 6 hours for preterm contractions.70

Nonsteroidal antiinflammatory drugs such as indomethacin have been used for tocolysis.69,70 Oral or rectal doses of 50 to 100 mg, followed by an oral dose of 25 to 50 mg every 6 hours, have been used. An increased rate of premature constriction of the ductus arteriosus has been noted in infants with indomethacin use after 32 weeks’ gestation and with use exceeding 48 hours.69 Indomethacin may be used when tocolysis is needed despite treatment with magnesium for neuroprotection because other agents, such as calcium channel blockers, can cause hypotension when administered concurrently with magnesium.

Other Drug Therapies for Preterm Labor Prevention

Infection is a potential cause of preterm labor. Antibiotics have been used, in addition to tocolytics and corticosteroids, to improve the outcome of preterm labor; however, a Cochrane review showed no reduction in the incidence of preterm delivery but a trend toward increased neonatal mortality. Therefore, routine use of antibiotics is not recommended. However, if a patient experiences preterm premature rupture of membranes (PPROM) before 34 weeks’ gestation, prophylactic antibiotics should be initiated. The combination of initial intravenous therapy (48 hours) with ampicillin and erythromycin, followed by 5 days of oral therapy with the same antibiotics, decreased the likelihood of chorioamnionitis and delivery for 3 weeks. Additionally, a reduction in major morbidities (i.e., death, respiratory distress syndrome, early sepsis, severe intraventricular hemorrhage, and necrotizing enterocolitis) was demonstrated.74

Progestosterone administration in the setting of prior preterm birth is much debated. Two large randomized, controlled trials produced significant findings. First, the administration of intramuscular 17-alpha-hydroxyprogesterone weekly (250 mg) starting between weeks 16 and 20 and continued through week 36 in high-risk women decreased the incidence of recurrent preterm birth.75 The second study replicated the findings using vaginal progesterone suppositories (100 mg).76 However, progesterone supplementation in women whose previous preterm birth occurred beyond 34 weeks produced similar rates of preterm delivery compared with placebo.77 The American College of Obstetrics and Gynecology currently recommends that progesterone supplementation be limited to women with a singleton pregnancy and a previous history of spontaneous preterm birth.78

Antenatal Corticosteroids

Use of antenatal corticosteroids for fetal lung maturation to prevent respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely is supported by a Cochrane review.79 The current clinical recommendation is to administer betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg intramuscularly every 12 hours for four doses to pregnant women between 26 and 34 weeks’ gestation who are at risk for preterm delivery within the next 7 days. Benefits from antenatal corticosteroids are believed to begin within 24 hours.

Salvage (“rescue”) treatment is administered to women who are at risk of delivering within 7 days but who have received a previous course of therapy. The incidence of respiratory distress syndrome was lower with the administration of rescue steroids compared with placebo (41.4% with betamethasone vs. 61.6% with placebo).80

GROUP B STREPTOCOCCUS INFECTION

Maternal infection with group B Streptococcus (GBS) is associated with invasive disease in the newborn.81,82 Women colonized with GBS have an increased risk for pregnancy loss, premature delivery, and transmission of the bacteria to the infant during delivery. Between 10% and 30% of pregnant women are colonized with GBS. The rate of invasive infection (defined as isolation of GBS from blood or other sterile body site excluding urine) in pregnant women is 0.12 per 1000 live births (range 0.11 to 0.14 per 1000 births). The incidence of early-onset disease in neonates, although higher than in pregnant women, has declined steadily from 1.8 per 1000 live births in 1990 to approximately 0.34 cases per 1000 live births during 2003 to 2005. The consequences of neonatal infections include bacteremia, pneumonia, meningitis, and fatality in the newborn.83 The case-fatality rate is approximately 4%.

Recommendations for prevention of GBS infection were updated in 2002.84 Universal prenatal screening for GBS colonization is recommended. Antibiotics are given if the woman previously gave birth to an infant with invasive GBS disease or in the presence of GBS bacteriuria. All other pregnant women should have a vaginal/rectal culture at 35 to 37 weeks’ gestation. If negative, antibiotics are not indicated. If a woman presents in labor and no screening information is available, antibiotics are given for fever greater than 100.4°F (38°C), membrane rupture at least 18 hours prior, or gestation under 37 weeks.

Penicillin G 5 million units given intravenously, followed by 2.5 million units given every 4 hours until delivery is the recommended treatment regimen.82 Alternatively, ampicillin 2 g can be given intravenously, followed by 1 g every 4 hours. For women with penicillin allergy but not at risk for anaphylaxis, cefazolin 2 g intravenously, followed by 1 g every 8 hours, is recommended. In women at high risk for anaphylaxis, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours is recommended. For penicillin-allergic women, GBS cultures should be sent for sensitivities. If resistant to clindamycin or erythromycin, vancomycin 1 g intravenously every 12 hours until delivery is appropriate.
CERVICAL RIPENING AND LABOR INDUCTION

Throughout gestation the cervix is closed and firm. During the last few weeks of pregnancy, the cervix softens and thins to facilitate labor. This process is mediated by hormonal changes, including final mediation by prostaglandins E₂ and F₂α, which increase collagenase activity in the cervix leading to thinning and dilating.

The rate of pregnancy induction ranges from 9.5% to 33.5%; the most common indications for induction are postdatism (beyond 42 weeks) and pregnancy-induced hypertension, which account for 80% of inductions. Other reasons for induction include suspected fetal growth retardation, maternal hypertension, premature rupture of membranes with no active onset of labor, and social factors. Contraindications include placenta previa, oblique or transverse lie, pelvic structure abnormality, ruptured umbilical cord, and active herpes. Concerns with induction of labor are ineffective labor and side effects, such as uterine hyperstimulation, that may adversely affect the infant and increase the likelihood of cesarean section.

Scoring systems have been used to determine the likelihood of successful labor induction. The Bishop scoring system is most commonly used and is based on five parameters: cervical dilation, cervical effacement (thinning), station of the baby’s head, consistency, and position of the cervix. A Bishop score under 6 indicates the need for cervical ripening while a score above 8 corresponds to a likely successful vaginal delivery.

A number of nonpharmacologic methods are used for cervical ripening. Castor oil, hot baths, sexual intercourse, and nipple stimulation all have been suggested for labor induction. Minimal evidence supports the efficacy of these methods. Use of a Foley catheter placed in an unfavorable cervix for ripening has been found as effective as prostaglandin E₂. Membrane stripping is safe and inexpensive.

Prostaglandin E₂ analogs (e.g., dinoprostone [Prepidil gel, Cervidil vaginal insert]) are commonly used for cervical ripening. Prepidil 500 mcg is administered intracervically. The dose may be repeated after 6 hours to a maximum of three doses in 24 hours. After administration, the patient remains supine for 30 minutes. Cervidil contains 10 mg dinoprostone with a slower, more constant release of medication than the gel. The insert is removed when labor begins or after 12 hours. Patients must be attached to a fetal heart rate monitor for the duration of Cervidil use and for 15 minutes after its removal.

Misoprostol, a prostaglandin E₁ analog, is an effective and inexpensive drug for cervical ripening and labor induction. Intravaginal administration of misoprostol is more effective than other prostaglandin agents and results in a shorter time to delivery. Oral misoprostol has been used successfully for cervical ripening and labor induction, but the evidence of safety is more extensive with intravaginal use. The most commonly encountered side effects are uterine hyperstimulation and meconium-stained amniotic fluid. Use of misoprostol is contraindicated in women with a previous uterine scar because of its association with uterine rupture, a catastrophic medical event.

CURRENT CONTROVERSY

Despite its efficacy and comparatively reasonable cost, some health systems have decided not to use misoprostol as an induction agent because of concerns about uterine rupture and lack of FDA indication for cervical ripening.

Progestogen inhibits uterine contractions. Preliminary studies show that mifepristone, an antiprogestosterone agent, compared with placebo results in a shorter time to delivery and fewer cesarean sections. Limited information on fetal and maternal outcomes is available because of the small sample sizes.

Oxytocin is the most commonly used agent for labor induction after cervical ripening. By the end of pregnancy, the number of oxytocin receptors has increased by 300-fold. A solution of 10 milliunits/mL is used for infusion. Oxytocin is effective in both low-dose (physiologic) and high-dose (pharmacologic) regimens.

LABOR ANALGESIA

In the first phase of labor, women perceive visceral pain caused by uterine contractions. Pain in the second phase of labor is associated with perineal stretching.

Nonpharmacologic Approaches to Analgesia

Women who receive continuous support from nurses, midwives, childbirth educators, or doulas [laywomen trained in labor support], have fewer operative vaginal deliveries, cesarean deliveries, and requests for pain medication. Warm water baths provide temporary pain relief but have not been shown to decrease the use of pharmacologic pain treatments. Intradermal injections of sterile water in the sacral area decrease back pain during labor for 45 to 120 minutes. However, requests for pain medication did not decrease in studies. Acupuncture has also been used for pain relief. Three randomized, controlled trials have shown that acupuncture decreases the need for analgesia, but more methodologically sound studies are needed. Use of audioanalgesia (music or white noise), relaxation and breathing techniques, application of heat and cold, aromatherapy, acupressure, and hypnosis have little to no evidence of effectiveness derived from randomized, controlled trials.

Pharmacologic Approaches to Labor Pain Management

The American College of Obstetricians and Gynecologists supports the concept that maternal request alone is a sufficient medical indication for labor analgesia. The two main types of pharmacologic approaches in the United States are parenteral opioids and epidural analgesia.

Parenteral opioids are commonly used to alleviate labor pain. In comparison with epidural analgesia, parenteral opioids have lower rates of oxytocin augmentation, result in shorter stages of labor, and require fewer instrumental deliveries.

Approximately 60% of women in the United States choose an epidural for pain relief during labor and report better pain relief than with other analgesic modalities. With epidural analgesia, a catheter is introduced into the epidural space and an opioid and/or an anesthetic (e.g., fentanyl and/or bupivacaine) is administered. Combined spinal–epidural analgesia consists of injecting a single opioid bolus into the subarachnoid space to provide instant pain relief with additional use of a local anesthetic epidural. Patient-controlled epidural analgesia allows the patient to control the amount and timing of the anesthetic; it results in a lower total dose of local anesthetics used over the course of labor compared with continuous epidural infusions.

Side effects of the regional anesthesia include hypotension, pruritus, and inability to void. Epidural analgesia is associated with prolongation of the first and second stages of labor, higher numbers of instrumental deliveries, and maternal fever. A rare complication of epidural anesthesia is puncture of the subarachnoid space leading to a severe headache, which occurs in approximately 1% of women. Other complications include hypotension, nausea, vomiting, itching, and urinary retention. Low back pain has not been associated with the use of epidural analgesia.
POSTPARTUM HEMORRHAGE

The placenta is delivered after the delivery of the baby and is referred to as the third stage of labor. Postpartum hemorrhage is an obstetrical emergency and is a major cause of morbidity and mortality.\textsuperscript{91} In the United States, the postpartum hemorrhage rate is approximately 1%–5% for vaginal deliveries.\textsuperscript{92} The traditional definition of postpartum hemorrhage is more than 500 mL of blood within 24 hours of a vaginal delivery or 1,000 mL after a cesarean section; however, other definitions have also been suggested. Risk factors include retained placenta, failure to progress during the second stage of labor, placenta previa, placenta accreta, lacerations, instrumental delivery, large for gestational newborn, hypertensive disorders, induction of labor, augmentation of labor with oxytocin, prior history, obesity, and high parity.\textsuperscript{93}

The most common cause of postpartum hemorrhage is uterine atony.\textsuperscript{91,93} Initial management should include oxytocin. Early clamping and cutting of the umbilical cord as well as controlled traction of the cord also decrease the incidence.\textsuperscript{91} Administration of a uterotonic medication (intramuscular oxytocin, ergotamine, or combination) before placental delivery and instituting active management of labor after all uncomplicated vaginal deliveries results in reduced maternal blood loss, fewer cases of postpartum hemorrhage, and less prolongation of the third stage of labor. Other uterotonic agents should be used if an inadequate response is attained with oxytocin alone. Methylergonovine, carboprost, misoprostol, and dinoprost have all been used; less evidence is available for misoprostol and dinoprostone.

POSTPARTUM ISSUES

DRUG USE DURING LACTATION

Most drugs transfer into breast milk, but breast-feeding may be continued in most circumstances. Healthcare providers should encourage breast-feeding women who require medications to continue breast-feeding whenever possible. Medications that are contraindicated or require the mother to pump and discard milk are few.

A wide variety of benefits (health, nutritional, immunologic, psychological, economic, developmental, and social) are imparted by breast-feeding to infants, mothers, and the family.\textsuperscript{94,20} Women should breast-feed exclusively for 6 months and continue until at least 12 months of age while other foods are introduced.\textsuperscript{96} Healthy People 2010 set a target of 75% of neonates being breast-fed at the time of birth and 50% of infants being breast-fed at 6 months of age.

Most drugs reach breast milk through passive diffusion, but other drug-related factors influence drug transfer from maternal circulation into breast milk, including (a) degree of protein binding in maternal plasma, (b) molecular weight, (c) lipid solubility (and corresponding fat content of milk), (d) maternal plasma concentration, (e) drug half-life, and (f) drug pH.\textsuperscript{94,26} The degree of protein binding to maternal plasma proteins is one of the most significant factors affecting drug transfer to breast milk; highly bound medications transfer in low amounts. Low-molecular-weight drugs passively diffuse into breast milk, but larger molecules are not likely to transfer in large amounts. Higher lipid solubility of drugs also increases the likelihood of transfer. Colostrum is secreted in the first couple of days after birth and has high quantities of immunoglobulins, maternal lymphocytes, and maternal macrophages. Compared with mature milk, colostrum is lower in fat content, so highly lipid soluble drugs achieve higher concentrations in mature milk. The higher the concentration of drug in the mother’s serum, the higher the concentration will be in the breast milk. As the drug is metabolized and excreted by the mother, the mother’s serum concentration drops, and drug in the breast milk may redistribute back into the mother’s bloodstream. Maternal plasma pH is 7.4, while the pH of breast milk ranges between 6.8 and 7.\textsuperscript{26} Weak bases are not ionized in the maternal circulation and easily transfer to breast milk. In the lower pH of breast milk, molecules become ionized and are less likely to diffuse back into maternal circulation (“ion trapping”). Likewise, drugs with longer half-lives are more likely to maintain higher levels in breast milk, resulting in greater exposure to the infant.

Infant-related factors may also influence the amount of drug ingested through breastfeeding.\textsuperscript{94} Both the frequency of feedings and the amount of milk ingested are important considerations. Exclusively breast-fed infants are more likely to ingest larger amounts of drugs than older infants who receive other foods. Drugs unstable in gastric acid (aminoglycosides, omeprazole, heparin, insulin) are less likely to be absorbed by infants. Finally, infants may vary in their ability to metabolize and excrete ingested medication. Premature and full-term infants may not have full renal and liver function.

Strategies for reducing the risk to the infant include selection of medications that would be considered safe for use in the infant.\textsuperscript{96} Drugs with shorter half-lives accumulate less, and those that are more protein bound do not cross into breast milk as well as those that are less protein bound. Drugs with lower oral bioavailability and lower lipid solubility are good choices. If the mother is using a once-daily medication, administration before the infant’s longest sleep period may be advised to increase the interval to the next feeding. For medications taken multiple times per day, administration immediately after breast-feeding provides the longest interval for back diffusion of drug from the breast milk to the mother’s serum. During short-term drug therapy, the mother can pump and discard milk to preserve her milk-producing capability if the medication is not considered compatible with breast-feeding.\textsuperscript{94}

Industry-based research on transfer of drugs into breast milk is scarce.\textsuperscript{94} Information from expert committees (e.g., American Academy of Pediatrics Committee on Drugs) and evidence-based textbooks or Web sites may be of assistance in providing reassurance regarding the safe use of medications in the lactating mother.

MASTITIS

Mastitis is inflammation in one breast.\textsuperscript{97} It can be infectious or noninfectious; the most common cause is milk stasis. About 10% of women in the United States experience mastitis during the first 3 months postpartum. Signs and symptoms include breast tenderness, redness, warmth, and flu-like symptoms.\textsuperscript{98} Risk factors for developing mastitis include breast engorgement, plugged milk ducts, and cracked nipples. Staphylococcus aureus is the most common bacterial cause of mastitis; E. coli and Streptococcus have also been implicated.\textsuperscript{97,99} A 10- to 14-day course of antibiotics is usually given for treatment of mastitis; penicillinase-resistant penicillins (e.g., dicloxacillin, oxacillin) and cephalosporins (e.g., cephalaxin) are frequently prescribed. Antiinflammatory drugs, such as ibuprofen, may provide some pain relief. Application of heat may also be helpful. Affected women should be counseled to continue breast-feeding from both breasts throughout treatment and to pump if breasts are not emptied completely with feedings.

POSTPARTUM DEPRESSION

Mood disorders in the postpartum period may include postpartum blues, postpartum depression, and postpartum psychosis.\textsuperscript{99} Postpartum blues is common, usually affecting 15% to 85% of new mothers within the first 10 days of delivery, and generally does not require treatment. Symptoms include anxiety, anger, and sadness.
Postpartum psychosis is more severe but is rare, affecting less than 1% of new mothers.

Postpartum depression affects up to 15% of women. Symptoms may develop during pregnancy or up to 6 months after delivery, although the strict definition for major depressive disorder after delivery specifies symptom occurrence within 1 month. Psychotherapy, including interpersonal psychotherapy, cognitive behavioral therapy, and group/family therapy, has been shown effective for treatment of postpartum depression.

In cases where pharmacotherapy is warranted, selection of medication with low transfer to breast milk is desirable. Sertraline is generally considered a first-line treatment because of its minimal transfer into breast milk and lack of reported adverse events in infants. Paroxetine and nortriptyline are considered second-line.

CURRENT CONTROVERSY

Treatment of postpartum depression in the breast-feeding mother poses challenges since all antidepressants transfer into breast milk, and long-term effects on cognitive, behavioral, motor, and neurologic development are unknown.

Postpartum depression poses significant risks to both mother and infant. Benefits and risks of pharmacologic and nonpharmacologic therapy must be weighed in selecting treatments for women with postpartum depression.

RELACTATION

Adequate milk removal from the breast by breastfeeding or pumping is necessary to maintain or increase milk production. Relactation is the process of increasing the breast milk supply for women who have failed lactogenesis II, who have inadequate milk production despite appropriate breastfeeding frequency or pumping, or who have weaned or never breast-fed after delivery. Lactation can also be induced in women who have not recently delivered a baby, such as adoptive mothers. The mainstay of therapy for this condition involves nipple stimulation either by the infant’s nursing or by pumping of the breast with a mechanical pump or the hand.

Metoclopramide can be used for relactation if nonpharmacologic measures are ineffective because of its stimulation of prolactin secretion. The most common dose is 10 mg orally three times daily for 7 to 14 days. Breast milk production can be increased up to 100% or more in women, although many of the studies have inadequate designs. Breast milk production may decrease after metoclopramide therapy is stopped, but production will continue if lactation has been established successfully.

CONCLUSION

Many women perceive a high inherent risk of birth defects with drug exposure during pregnancy. This perception, linked with a high rate of unplanned pregnancies, may create anxiety because of drug exposure prior to the discovery of pregnancy.

Some medications are considered safe for use in pregnancy because of frequent use with no apparent increase in the rate of congenital problems. In some cases, ensuring the health of the mother and the fetus will require selection or continuation of medications that have been associated with a higher risk of adverse effects to the fetus. In these instances, realistic information about the types and likelihood of adverse effects will aid the patient and her family in making decisions.

Healthcare providers who care for pregnant women must work in collaboration to seek, evaluate, and present the most contemporary and accurate information to their patients. Use of technology to access evidence-based resources, databases related to drug use in pregnancy, and primary and secondary literature may assist healthcare practitioners in accessing relevant medication information to manage drug therapy needs during pregnancy and lactation.

KEY CONCEPTS

1. The attitude of the patient and sexual partner toward contraceptive methods, efficacy rate, the reliability of the patient in using the method correctly (which may affect the effectiveness of the method), noncontraceptive benefits, and the patient’s ability to pay must be considered when selecting a contraceptive method.

2. Patient-specific factors (e.g., frequency of intercourse, age, smoking status, and concomitant diseases, or medications) must be evaluated when selecting a contraceptive method.

3. Adverse effects or difficulties using the chosen method should be monitored carefully and managed in consideration of patient-specific factors.

4. Accurate and timely counseling on the optimal use of the contraceptive method and strategies for minimizing sexually transmitted diseases must be provided to all patients when contraceptives are initiated and on an ongoing basis.

5. Emergency contraception may prevent pregnancy after unprotected intercourse or when regular contraceptive methods have failed.

Unintended pregnancy is a significant public health problem. In the United States, approximately 62 million women are of childbearing age, and approximately 6 million become pregnant each year. The most recent data reveal that 31% of pregnancies are unintended, with the highest rates occurring in women aged 25 to 44 years (38%). About half of all unintended pregnancies end in abortion, and half also occurred in sexually active couples who claimed they used some method of contraception. If the goal of contraception—for pregnancies to be planned and desired—is to be realized, education on the use and efficacy of contraceptive methods must be improved.

ETIOLOGY AND PATHOPHYSIOLOGY

Comprehension of the hormonal regulation of the normal menstrual cycle is essential to understanding contraception in women (Fig. 88–1). The cycle of menstruation begins with menarche, usually around age 12 years, and continues to occur in nonpregnant women until menopause, usually around age 50 years. Factors such as race, body weight, medical conditions, and family history can affect the menstrual cycle. The cycle includes the vaginal discharge of sloughed endometrium called menses. The menstrual cycle comprises three phases: follicular (or preovulatory), ovulatory, and luteal (or postovulatory).

THE MENSTRUAL CYCLE

The first day of menses is referred to as day 1 of the menstrual cycle and marks the beginning of the follicular phase. The follicular phase continues until ovulation, which typically occurs on day 14. The time after ovulation is referred to as the luteal phase, which lasts until the beginning of the next menstrual cycle. The median menstrual cycle length is 28 days, but it can range from 21 to 40 days. Generally, variation in length is greatest in the follicular phase, particularly in the years immediately after menarche and before menopause.

The menstrual cycle is influenced by the hormonal relationships among the hypothalamus, anterior pituitary, and ovaries. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion. These GnRH bursts stimulate the anterior pituitary to secrete bursts of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). FSH and LH direct events in the ovarian follicles that result in the production of a fertile ovum.

Follicular Phase

In the first 4 days of the menstrual cycle, FSH levels rise and allow the recruitment of a small group of follicles for continued growth and development (Fig. 88–1). Between days 5 and 7, one follicle becomes dominant and later ruptures, releasing the oocyte. The dominant follicle develops increasing amounts of estradiol and inhibin, which cause a negative feedback on the hypothalamic secretion of GnRH and pituitary secretion of FSH, causing atresia of the remaining follicles recruited during the cycle.

Once the follicle has received FSH stimulation, it must receive continued FSH stimulation or it will die. FSH allows the follicle to enlarge and synthesize estradiol, progesterone, and androgen. Estradiol stops the menstrual flow from the previous cycle, thickening the endometrial lining of the uterus to prepare it for embryonic implantation. Estrogen is responsible for increased production of thin, watery cervical mucus, which will enhance sperm transport during fertilization. FSH regulates the aromatase enzymes that convert androgens to estrogens in the follicle. If a follicle has insufficient aromatase, the follicle will not survive.

Ovulation

When estradiol levels remain elevated for a sustained period of time, the pituitary releases a midcycle LH surge (Fig. 88–1). This LH surge stimulates the final stages of follicular maturation and
ovulation (follicular rupture and release of the oocyte). On average, ovulation occurs 24 to 36 hours after the estradiol peak and 10 to 16 hours after the LH peak. The LH surge, which occurs 28 to 32 hours before a follicle ruptures, is the most clinically useful predictor of approaching ovulation. After ovulation, the oocyte is released and travels to the fallopian tube, where it can be fertilized and transported to the uterus for embryonic implantation. Conception is most successful when intercourse takes place from 2 days before ovulation to the day of ovulation.

Luteal Phase

After rupture of the follicle and release of the ovum, the remaining luteinized follicles become the corpus luteum, which synthesizes androgen, estrogen, and progesterone (Fig. 88–1). Progesterone helps to maintain the endometrial lining, which sustains the implanted embryo and maintains the pregnancy. It also inhibits GnRH and gonadotropin release, preventing the development of new follicles. If pregnancy occurs, human chorionic gonadotropin prevents regression of the corpus luteum and stimulates continued production of estrogen and progesterone secretion to maintain the pregnancy until the placenta is able to fulfill this role.

If fertilization or implantation does not occur, the corpus luteum degenerates, and progesterone production declines. The life span of the corpus luteum depends on the continuous presence of small amounts of LH, and its average duration of function is 9 to 11 days. As progesterone levels decline, endometrial shedding (menstruation) occurs, and a new menstrual cycle begins. At the end of the luteal phase, when estrogen and progesterone levels are low, FSH levels start to rise, and follicular recruitment for the next cycle begins.

EPIEMIOLOGY

Contraception implies the prevention of pregnancy following sexual intercourse by inhibiting viable sperm from coming into contact with a mature ovum (i.e., methods that act as barriers or prevent ovulation) or by preventing a fertilized ovum from implanting successfully in the endometrium (i.e., mechanisms that create an unfavorable uterine environment). These methods differ in their relative effectiveness, safety, and patient acceptability.

The actual effectiveness of any contraceptive method is difficult to determine because many factors affect contraceptive failure.
A failure in patients who use the contraceptive agent properly is considered a method failure or perfect-use failure. It is also important to consider user failure or typical-use failure rates, which are usually higher because they take into account the user’s ability to follow directions correctly and consistently.\(^3,4\)

### CLINICAL PRESENTATION

Most health maintenance annual visits should include assessment of and counseling about reproductive health. Clinicians may use this opportunity to provide contraception and educate patients on prevention of sexually transmitted diseases (STDs). Traditionally, hormonal contraception is provided subsequent to breast and pelvic examinations. However, the need for the physical examination may delay access to contraception, resulting in unintended pregnancies. In addition, requiring breast and pelvic examinations prior to prescription of hormonal contraception reinforces the incorrect perception that these methods of contraceptives are harmful. Therefore, the American Congress of Obstetrics and Gynecology (ACOG) and other national organizations allow provision of hormonal contraception after a simple medical history and blood pressure measurement.\(^6\) Other preventive measures, such as pelvic and breast examinations, provision of the human papillomavirus vaccine, and screening for cervical neoplasia can be accomplished during routine annual office visits.\(^6–9\)

### TREATMENT

#### DESIRED OUTCOME

The obvious goal of treatment with all methods of contraception is to prevent pregnancy. However, many health benefits are associated with contraceptive methods, including prevention of STDs (with condoms), improvements in menstrual cycle regularity (with hormonal contraceptives), improvements in certain health conditions (with oral contraceptives [OCs]), and management of perimenopause.\(^5\)

#### NONPHARMACOLOGIC THERAPY

##### Periodic Abstinence

Motivated couples may use the abstinence (rhythm) method of contraception, avoiding sexual intercourse during the days of the menstrual cycle when conception is likely to occur. Physiologic changes, such as basal body temperature and cervical mucus are used during each cycle to determine the fertile period. The major drawbacks are the relatively high pregnancy rates and avoidance of intercourse for several days during each menstrual cycle.\(^3,4\)

##### Barrier Techniques

The effectiveness of barrier methods depends almost exclusively on motivation to use them consistently and correctly.\(^3,4\) These methods include condoms, diaphragms, cervical caps, and sponges (Table 88–1). A major disadvantage is higher failure rates than most hormonal contraceptives; thus, provision of counseling and an advanced prescription for emergency contraception (EC) are recommended for all patients using barrier methods as their primary means of contraception.

Condoms create a mechanical barrier, preventing direct contact of the vagina with semen, genital lesions, and infectious secretions.\(^3,4\) Most condoms in the United States are made of latex, which is impermeable to viruses. A small proportion are made from lamb intestine, which is not impermeable to viruses. Synthetic condoms manufactured from polyurethane are another option; these condoms are latex-free and do protect against viruses. Condoms are used worldwide as protection from STDs including human immunodeficiency virus (HIV). When condoms are used in conjunction with any other barrier method, their effectiveness theoretically approaches 98%. Spillage of semen or perforation and tearing of the condom can occur, but proper use minimizes these problems.\(^4\) Mineral oil–based vaginal drug formulations (e.g., Cleocin, Premarin, and Monistat), lotions, or lubricants can decrease the barrier strength of latex, thus making water-soluble lubricants (e.g., Astroglide, K-Y Jelly) preferable.\(^4\) Condoms with spermicides are no longer recommended because they provide no additional protection against pregnancy or STDs and may increase vulnerability to HIV.\(^1\)

The female condom (FC, formerly Reality brand) is a prelubricated, loose-fitting polyurethane sheath, closed at one end, with flexible rings at both ends.\(^3,4\) Properly positioned, the ring at the closed end covers the cervix, and the sheath lines the walls of the vagina. The outer ring remains outside the vagina, covering the labia. The pregnancy rate is reported to be 21% in the first year of typical use. Male and female condoms should not be used together, as slippage and device displacement may occur.

The diaphragm, a reusable dome-shaped rubber cap with a flexible rim that is inserted vaginally, fits over the cervix in order to decrease access of sperm to the ovum. The diaphragm requires a prescription from a physician who has fitted the patient for the correct size.\(^3,4\) Its effectiveness depends on its function as a barrier and on the spermicidal cream or jelly placed in the diaphragm before insertion. The diaphragm may be inserted up to 6 hours before intercourse and must be left in place for at least 6 hours afterward. However, leaving it in place for more than 24 hours is not recommended due to the potential for toxic shock syndrome. With subsequent acts of intercourse, the diaphragm should be left in place, and a condom should be used for additional protection.\(^3\)

The cervical cap is a soft, deep cup with a firm round rim that is smaller than a diaphragm and fits over the cervix like a thimble.\(^3,4\) Currently, two latex-free cervical caps are available by prescription in the United States: the FemCap and the Lea’s Shield.\(^3\) The FemCap is available in three sizes and should be filled with spermicide prior to insertion.\(^3,4\) It is held in place against the cervix until the cap is removed. The Lea’s Shield is available in only one size and is held in place by the vaginal wall; therefore, cervical size is not a factor.\(^3\) Both caps can be inserted 6 hours prior to intercourse and should not be removed for at least 6 hours after intercourse. They may remain in place for multiple episodes of intercourse without adding more spermicide but should not be worn for more than 48 hours at a time to reduce the risk of toxic shock syndrome. Failure rates are higher than with other methods. Some studies have shown an increased risk of cervical dysplasia, so users must have a repeat Papanicolaou (Pap) smear 3 months after starting to use a cervical cap.\(^3\) Diaphragms and cervical caps do not protect against some STDs including HIV, thus condoms should also be used.

#### PHARMACOLOGIC THERAPY

##### Spermicides

Spermicides, most of which contain nonoxynol-9, are chemical surfactants that destroy sperm cell walls and act as barriers that prevent sperm from entering the cervical os.\(^1\) They are available as creams, films, foams, gels, suppositories, sponges, and tablets.\(^3,4\) Spermicides offer no protection against STDs. In fact, when used frequently (more than 2 times per day), nonoxynol-9 may increase the risk of transmission of HIV by causing small disruptions in the
A variety of progestins are available in the United States and they vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects. Progestins provide most of the contraceptive effect, by thickening cervical mucus to prevent sperm penetration, slowing tubal motility and delaying sperm transport, and inducing endometrial atrophy. Progestins block the LH surge, therefore inhibiting ovulation. Estrogens suppress FSH release from the pituitary, which may contribute to blocking the LH surge and preventing ovulation. However, the primary role of estrogen in hormonal contraceptives is to stabilize the endometrial lining and provide cycle control.

HIV, human immunodeficiency virus; STD, sexually transmitted disease; TSS, toxic shock syndrome; UTI, urinary tract infection.
*Failure rates in the United States during first year of use.
*Failure rate with FemCap reported to be 29% per package insert.
*Failure rate with Today sponge reported to be 20% in parous women.
*Failure rate with Today sponge reported to be 32% in parous women.
*Data from Hatcher and Nelson, and Dickey.

**Spermicide-Implanted Barrier Techniques**

The vaginal contraceptive sponge (Today) contains 1 g of the spermicide nonoxynol-9. It has a concave dimple on one side to fit over the cervix and a loop on the other side to facilitate removal. After being moistened with water, the sponge is inserted into the vagina up to 6 hours before intercourse. The sponge provides protection for 24 hours, regardless of the frequency of intercourse during this time. After intercourse, the sponge must be left in place for at least 6 hours before removal and should not be left in place for more than 24 to 30 hours to reduce the risk of toxic shock syndrome. Sponges should not be reused, after removal they should be discarded. The sponge comes in one size and is available over the counter (OTC).

**Hormonal Contraception**

Hormonal contraceptives contain a combination of estrogen and progestin or a progestin alone. Oral contraceptive preparations first became available in the 1960s, but options have expanded to include a transdermal patch, a vaginal contraceptive ring, and long-acting injectable, implantable, and intrauterine contraceptives.

Combined hormonal contraceptives (CHCs) work primarily before fertilization to prevent conception. Progestins provide most of the contraceptive effect, by thickening cervical mucus to prevent sperm penetration, slowing tubal motility and delaying sperm transport, and inducing endometrial atrophy. Progestins block the LH surge, therefore inhibiting ovulation. Estrogens suppress FSH release from the pituitary, which may contribute to blocking the LH surge and preventing ovulation. However, the primary role of estrogen in hormonal contraceptives is to stabilize the endometrial lining and provide cycle control.

**Estrogens** Two synthetic estrogens found in hormonal contraceptives available in the United States are ethinyl estradiol (EE) and mestranol. Mestranol, must be converted by the liver to EE before it is pharmacologically active and is 50% less potent than EE. Most combined OCs, transdermal patch, and vaginal ring contain estrogen at doses of 20 to 50 mcg of EE.

**Progestins** A variety of progestins are available in the United States and they vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects. Estrogenic and antiestrogenic properties are secondary to the extent of progestins’ metabolism to estrogenic substances. Androgenic activity is dependent upon two variables: the presence of sex hormone (testosterone) binding globulin (SHBG-TBG) and...
the androgen:progesterone activity ratio. If the amount of SHBG-TBG is decreased, free testosterone levels increase and androgenic side effects are more prominent.5

Considerations with Combined Hormonal Contraceptive Use. 1 When selecting a CHC, clinicians are challenged by weighing the benefits and risks associated with the many formulations available. The clinician must determine if the form of contraception is appropriate based upon the patient’s lifestyle and potential adherence. A complete medical examination and Pap smear are not necessary before a CHC is prescribed. A medical history and blood pressure measurement should be obtained before prescribing a CHC, along with a discussion of the benefits, risks, and adverse effects with each patient.3,5,14–16 For example, OCs are associated with noncontraceptive benefits, including relief from menstruation-related problems (e.g., decreased menstrual cramps, decreased ovulatory pain [mittelschmerz], and decreased menstrual blood loss), improvement in menstrual regularity and decreased iron deficiency anemia. Women who take combination OCs have a reduced risk of ovarian and endometrial cancer. There is a 50% reduction in risk in women who have used OCs for 5 years or more, and protection may persist for more than 10 years post-use. Combination OCs may also reduce the risk of ovarian cysts, ectopic pregnancy, pelvic inflammatory disease, endometriosis, uterine fibroids, and benign breast disease. The CHC transdermal patch and vaginal ring are other combined hormonal options that may be more convenient for women than taking a tablet each day.

2 2 Adverse effects may hinder adherence and therefore efficacy, so they should be discussed prior to initiating a hormonal contraceptive agent (Table 88–2). Excessive or deficient amounts of estrogen and progestin are related to the most common adverse effects.3–5 The CHC vaginal ring may be uncomfortable for some women and cause vaginal discharge. The CHC patch may cause irritation and now has information added to product labeling regarding the increased potential for thromboembolism.

An important concern regarding the use of CHCs is the lack of protection against STDs. Because of their high efficacy in preventing pregnancy, patients may choose not to use condoms. In addition to public health awareness, clinicians must encourage patients to use condoms for prevention of STDs. OCs have an extensive history of safety concerns, which traditionally were related to high dose estrogen tablets. To replace the traditional absolute and relative contraindications to the use of OCs, the WHO developed a graded list of precautions for clinicians to consider when initiating CHCs (Table 88–3).4,12,13

In addition to the WHO precautions, the ACOG provides information for clinicians to use when selecting CHCs for women with coexisting medical conditions.17 Overall, the health risks associated with pregnancy, the specific health risks associated with CHCs and the noncontraceptive benefits of CHCs should be factored into risk-to-benefit considerations.

Women Older Than 35 Years. Use of CHC in women older than 35 years of age is controversial. Older women, especially women in their 40s retain a level of fertility even in the perimenopausal state and should use contraception to prevent pregnancy. Formulations with lower doses of estrogen (less than 30 mcg) have increased the use of CHCs in these women. In addition to the benefit of pregnancy prevention, they may improve or decrease the chance of developing perimenopausal and menopausal symptoms and increase bone mineral density (BMD). However, the benefits of using CHCs must be weighed against the risks in women older than 35. The increased risk of cardiovascular disease and venous thromboembolism (VTE) should be considered especially in perimenopausal women older than 40. Older data suggests an increased risk of myocardial infarction (MI) in older women using CHCs, although many women in these studies were current smokers and used older formulations containing higher doses (greater than 50 mcg) of estrogen. More recent data does not support the increased risk of cardiovascular disease when low dose formulations of CHCs are used in healthy, non-obese women. Other concerns include the increased risk of ischemic stroke in women with migraines and the increased risk of breast cancer in older women.5,16–18

The risks and benefits of using CHCs in women greater than 35 must be considered on an individual basis. The ACOG and WHO recommend that use of CHCs (with less than 50 mcg of estrogen) may be considered in healthy nonsmoking women. Furthermore, they recommend against the use of CHCs in women older than 35 with migraine (with or without aura), hypertension, dyslipidemia, current smoker, and type 1 or type 2 diabetes mellitus.13,17

Smoking. In early studies, OCs with 50 mcg EE or more were associated with MI in women who smoked cigarettes.4,14,16,17 U.S. case-control studies have found that both nonsmoking and smoking women, regardless of age, taking OCs with less than 50 mcg EE did not have an increased risk of MI or stroke. However, these studies included few women older than 35 years who were smokers. European studies, with a higher population of older smoking women, demonstrated an increased risk of MI in this population.

CHC, combined hormonal contraceptive; IUD, intrauterine device; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive.

*CHC regimens should be continued for at least 3 months before adjustments are made based on adverse effects.

Data from Hatcher and Nelson,5 and Dickey.3
Therefore, practitioners should prescribe CHC with caution, if at all, to women older than 35 years who smoke. The WHO precautions further state that smoking 15 or more cigarettes per day by women in this age group is a contraindication to CHC, and that the risks generally outweigh the benefits of CHC in those who smoke. Women with hypertension who smoke should not use CHCs. Women with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC containing drospirenone, which has antialdosterone properties.

**Dyslipidemia.** Generally, synthetic progestins adversely affect lipid metabolism by decreasing high-density lipoprotein (HDL) and increasing low-density lipoprotein (LDL). Estrogens tend to have more beneficial effects by enhancing removal of LDL and increasing HDL levels. Estrogens may moderately increase triglycerides. As a net result, most low-dose CHCs have no significant impact on HDL, LDL, triglycerides, or total cholesterol. CHCs containing more androgenic progestins (e.g., levonorgestrel) may result in lower HDL levels in some patients. Although the lipid effects of CHCs theoretically can influence cardiovascular risk, the mechanism of increased cardiovascular disease in CHC users is believed to be due to thromboembolic and thrombotic changes, not athero-

CHC, combined hormonal contraception; HIV, human immunodeficiency virus.

Data from: Hatcher and Nellson; Dickey; World Health Organization.

This has been documented in both normotensive and mildly hypertensive women given a 30 mcg EE OC. In case-control studies of women with hypertension, OCs have been associated with an increased risk of MI and stroke. Use of low dose CHC is acceptable in women younger than 35 years with well-controlled and frequently monitored hypertension. If a CHC-related increase in blood pressure occurs, discontinuing the CHC usually restores blood pressure to pretreatment values within 3 to 6 months. Hypertensive women who have end-organ vascular disease or who smoke should not use CHCs. Women with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC containing drospirenone, which has antialdosterone properties.

**Hypertension.** CHCs can cause small increases (i.e., 6–8 mm Hg) in blood pressure, regardless of estrogen dosage. This has been documented in both normotensive and mildly hypertensive women given a 30 mcg EE OC. In case-control studies of women with hypertension, OCs have been associated with an increased risk of MI and stroke. Use of low dose CHC is acceptable in women younger than 35 years with well-controlled and frequently monitored hypertension. If a CHC-related increase in blood pressure occurs, discontinuing the CHC usually restores blood pressure to pretreatment values within 3 to 6 months. Hypertensive women who have end-organ vascular disease or who smoke should not use CHCs. Women with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC containing drospirenone, which has antialdosterone properties.

**Dyslipidemia.** Generally, synthetic progestins adversely affect lipid metabolism by decreasing high-density lipoprotein (HDLD) and increasing low-density lipoprotein (LDL). Estrogens tend to have more beneficial effects by enhancing removal of LDL and increasing HDL levels. Estrogens may moderately increase triglycerides. As a net result, most low-dose CHCs have no significant impact on HDL, LDL, triglycerides, or total cholesterol. CHCs containing more androgenic progestins (e.g., levonorgestrel) may result in lower HDL levels in some patients. Although the lipid effects of CHCs theoretically can influence cardiovascular risk, the mechanism of increased cardiovascular disease in CHC users is believed to be due to thromboembolic and thrombotic changes, not athero-
sclerosis. Women with controlled dyslipidemia can use low dose CHCs, although periodic fasting lipid profiles are recommended. Women with uncontrolled dyslipidemia (LDL greater than 160 mg/dL [4.14 mmol/L], HDL less than 35 mg/dL [0.91 mmol/L], triglycerides greater than 250 mg/dL [2.83 mmol/L]) and additional risk factors (e.g., coronary artery disease, diabetes, hypertension, smoking, or positive family history) should use an alternative method of contraception.

**Diabetes.** Any effect of CHCs on carbohydrate and lipid metabolism is thought to be due to the progestin component. However, with the exception of some levonorgestrel-containing products, formulations containing low doses of progestins do not significantly alter insulin, glucose, or glucagon release after a glucose load in healthy women or in those with a history of gestational diabetes. The new progestins are believed to have little, if any, effect on carbohydrate metabolism. CHCs do not appear to alter the hemoglobin A1c values or accelerate the development of microvascular complications in women with type 1 diabetes. In the Nurses’ Health Study, women who used OCs did not demonstrate any increased risk of developing type 2 diabetes. Therefore, nonsmoking women younger than 35 years with diabetes but not associated vascular disease can safely use CHCs. Diabetic women with vascular disease (e.g., nephropathy, retinopathy, neuropathy, or other vascular disease or diabetes of more than 20 years’ duration) should not use CHCs.

**Migraine Headaches.** Women with migraine headaches may experience a decreased or an increased frequency of migraine headaches when using CHCs. Headaches may even occur during the hormone-free interval. Studies have demonstrated a higher risk of stroke in women experiencing migraine with aura compared to women with simple migraine. In population-based studies, the risk of stroke in women with migraines has been elevated twofold to threefold. However, given the low absolute risk of stroke in young women (age less than 35 years), the ACOG recommends considering CHCs in healthy, nonsmoking women with migraine headaches without aura. Women of any age who have migraine with aura should not use CHC. Women who develop migraines (with or without aura) while receiving CHC should discontinue use and consider a progestin-only option.

**Breast Cancer.** Worldwide epidemiologic data from 54 studies in 25 countries (many of which studied high dose OCs) were collected to assess the relationship between OCs and breast cancer. Overall, investigators noted a small increased risk of breast cancer associated with current or recent use, but OCs did not further increase risk in women with a history of benign breast disease or a family history of breast cancer. A more recent U.S.-based case-control study found no association between overall breast cancer and current or past OC use. This study also found no association between depomedroxyprogesterone acetate (DMPA) and breast cancer. Although some studies have found differences in risk of breast cancer based on the presence of BRCA1 and BRCA2 mutations, the most recent cohort study found no association with low dose OCs and the presence of either mutation. The choice to use CHCs should not be affected by the presence of benign breast disease or a family history of breast cancer with either mutation. The WHO precautions state that women with a recent personal history of breast cancer should not use CHCs, but that CHCs can be considered in women without evidence of disease for 5 years.

**Thromboembolism.** Estrogens increase hepatic production of factor VII, factor X, and fibrinogen in the coagulation cascade, therefore increasing the risk of thromboembolic events (deep vein thrombosis, pulmonary embolism). These risks are increased in women who have underlying hypercoagulable states (e.g., deficiencies in antithrombin III, protein C, and protein S; factor V Leiden mutations, prothrombin G2010 A mutations) or who have acquired conditions (e.g., obesity, pregnancy, immobility, trauma, surgery, and certain malignancies) that predispose them to coagulation abnormalities. In U.S.-case-control studies, the risk of VTE in women currently using low dose OCs (less than 50 mcg EE) was 4 times the risk in nonusers. However, this risk is less than the risk of VTE incurred during pregnancy. OCs containing desogestrel have been associated with a 1.7 to 19 times higher risk of VTE than OCs containing levonorgestrel. Some clinicians argue that this difference reflects preferential prescribing of the newer, and perceived safer, progestin products for women at greater risk for VTE. Estrogen exposure in women using transdermal CHC may be greater than that in women taking OCs or using the vaginal ring over time, but the absolute risk of VTE in this population is unknown. Therefore, CHCs are contraindicated in women with a history of thromboembolic events and in those at risk due to prolonged immobilization with major surgery unless they are currently taking anticoagulants. Women with familial coagulopathies are at particular risk during pregnancy, given the risk of VTE and of fetal exposure to warfarin. CHCs reduce menstrual blood loss and are safe for use by women with appropriate anticoagulation. EC has not been associated with an increased risk of thromboembolic events.

**Obesity.** The prevalence of obesity continues to rise each year among all age groups including women of childbearing age. It has been hypothesized that women with increased body weight have increased basal metabolic rates and induction of hepatic enzymes, leading to increased hormonal clearance and decreased serum concentrations of hormonal contraceptives. In addition, women who are obese have more adipose tissue, increasing hormonal sequestration, and decreased free hormone serum concentrations resulting in lower efficacy. In one recent case-control study, the odds ratio for pregnancy was 1.58 (CI, 1.11-2.24) and 1.72 (CI, 1.04-2.82) in women with a body mass index greater than 27 kg/m² or greater than 32 kg/m², respectively. The authors concluded that this association translates to an additional 2 to 4 pregnancies per 100 woman-years of use in overweight or obese users. This decreased efficacy may be a particular issue with the low dose OCs. Along these same lines, ACOG recommends that the transdermal contraceptive patch should not be used as a first-line option in women weighing greater than 90 kg (198 lbs). It is important to note, however, that the overall risk of decreased efficacy is relatively small when compared to the alternative of increased pregnancy rates when women do not use contraception. It should be noted that increased pregnancy rates have not been demonstrated in obese women using DMPA or the levonorgestrel IUD.

Obese women are also at risk of VTE. In a few population-based case-control studies, obesity (defined as a BMI greater than or equal to 30 kg/m²) was associated with an increased risk of VTE when all other factors, including age and estrogen dosage, were controlled. The mechanism to support the evidence is unclear. Women should be counseled on the risk and consider alternative contraceptive methods on an individual basis.

**Systemic Lupus Erythematosus.** Contraception is important in women with systemic lupus erythematosus (SLE) because the risks associated with pregnancy are high in this population. Historically, clinicians have thought that CHCs exacerbated the symptoms of SLE. However, trials have shown that OCs do not increase the risk of flare among women with stable SLE and without antiphospholipid/anticardiolipin antibodies. Because 25% of women with SLE who become pregnant choose to terminate the pregnancy, effective contraception is essential for these patients. CHCs should be avoided in women with SLE and antiphospholipid antibodies or vascular complications; progestin-only contraceptives can be used in this situation.
**Sickle Cell Disease.** Two controlled trials have demonstrated a reduction in risk of vasoocclusive crises in women with sickle cell disease using DMPA as the method of contraception. Theoretical concerns about the effects of CHCs on platelet activation and red cell deformity, for example, led clinicians to avoid their use in women with sickle cell disease. Because pregnancy carries such a high risk in this population, contraception with DMPA should be considered.

**Oral Contraceptives**

1. With perfect-use, OCs have a 99% efficacy rate, but with typical-use up to 8% of users may become pregnant. The OCs currently available are modifications of the original products introduced in the 1960s and contain significantly less estrogen and progestin. High-dose formulations were associated with vascular and embolic events, cancers, and significant side effects, but reductions in hormone doses have been associated with fewer complications.

Monophasic OCs contain the same amounts of estrogen and progestin for 21 days, followed by 7-day placebo phase. Biphasic and triphasic pills contain variable amounts of estrogen and progestin for 21 days, also followed by a 7-day placebo phase. There are no published data demonstrating increased safety or significant differences in bleeding patterns with the multiphasic tablets compared to monophasic tablets. Extended-cycle tablets and continuous combination regimens may offer some benefits for patients in terms of side effects and convenience. One particular extended-cycle OC increases the number of hormone-containing pills from 21 to 84 days, followed by a 7-day placebo phase, resulting in four menstrual cycles per year. Another product provides hormone-containing tablets daily throughout the year. Women taking extended-cycle and continuous-cycle tablets tend to have a decreased amount of bleeding over time, often leading to amenorrhea. Continuous combination regimens provide OCs for 21 days, then very low-dose estrogen and progestin for an additional 4 to 7 days (during the traditional placebo phase).

OCs containing newer progestins (desogestrel, drospirenone, gestodene, and norgestimate) are referred to as third-generation OCs. These progestins are potent progesterational agents that have no estrogenic effects and are less androgenic compared with levonorgestrel on a weight basis. Therefore, these agents are thought to have improved side-effect profiles, such as improving mild to moderate acne. Drospirenone also has antimineralocorticoid and anti-aldosterone activities, which may result in less weight gain compared to use of OCs containing levonorgestrel. Few clinical trials have compared OCs and sample sizes are small, so the actual relevance of these differences in progestins remains unknown. A review by the Cochrane Library concluded that there was no evidence supporting a causal association between combination OCs or combination skin patches and weight gain.

**Choice of Oral Contraceptive.** Because all combined OCs are similarly effective in preventing pregnancy, the initial choice is based on the hormonal content and dose, preferred formulation, and coexisting medical conditions. In women without coexisting medical conditions, an OC containing 35 mcg or less of EE and less than 0.5 mg of norethindrone or an equivalent progestin is recommended. This strategy is based on evidence that complications and side effects from CHC (i.e., VTE, stroke, or MI) result from excessive hormonal content. Adolescents, underweight women (less than 50 kg [110 lbs]), women older than 35 years, and those who are perimenopausal may have fewer side effects with OCs containing 20 to 25 mcg of EE. With nonadherence to OCs, the risk of pregnancy may be greater in women taking OCs containing less than 35 mcg of EE. Overweight and obese women may have higher contraceptive failure rates with low-dose OCs and may benefit from pills containing at least 35 mcg of EE. Women with regular heavy menses initially may benefit from a 50 mcg EE OC because of their higher endometrial activity and women with regular light menses can be started on 20 mcg EE OCs. Women with oily skin, acne, or hirsutism should be given low androgenic OCs.

Conventional regimens (21 days of active pills, 7 days of placebo) provide predictable menses. Because monophasic OCs may be easier to take, easier to identify/manage side effects, and easier to manipulate to alter the timing of the menstrual cycle, they are preferred over multiphasic OCs.

Extended-cycle OCs either eliminate or reduce the number of menstrual cycles per year, leading to less premenstrual symptoms and dysmenorrhea. Commercially available extended-cycle OCs are available, or monophasic 28-day OCs can be cycled by skipping the 7-day placebo phase. With continued use of extended-cycle OCs for 1 year, no significant changes adverse effects have been noted. However, long-term studies have not been performed to assess the risk of cancer, VTE, or changes.

<sup>e</sup>Percentage reporting after 6–12 months of use.
<sup>f</sup>Contains folate supplementation (levomefolate calcium 0.451mg).

Data from Hatcher and Nelson.<sup>4</sup> Dickey.<sup>5</sup> and Anonymous.<sup>14</sup>
Coexisting medical conditions and their impact on CHC use have been previously addressed. Women with migraine headaches, history of VTE, cardiovascular disease, cerebrovascular disease, and SLE with vascular disease are good candidates for progestin-only methods. In addition, women with a history of estrogen dependent cancer, smokers over the age of 35, and those who are postpartum and/or breastfeeding should use progestin-only or nonhormonal methods.\(^4\)\(^,\)\(^5\)

Managing Oral Contraceptive Side Effects. Many symptoms occurring with early OC use (e.g., nausea, bloating, breakthrough bleeding) improve spontaneously by the third cycle of use after adjusting to the altered hormone levels.\(^3\)\(^-\)\(^5\) Women should be counseled to continue their OC for 2 to 3 months before a change is made to adjust the hormonal content. However, a large majority of women who discontinue OCs do so because of the side effects. Patient education and early reevaluation within 3 to 6 months are necessary to identify and manage adverse effects, in an effort to improve adherence. A list of OC-related side effects and their management is given in Table 88–2.

If the patient has symptoms related to OC use, it is necessary to determine if the symptom indicates the presence or potential development of a serious illness (Table 88–5).\(^4\)\(^,\)\(^5\) Patients should be instructed to immediately discontinue CHCs if they experience warning signs, described as ACHES (abdominal pain, chest pain, headaches, eye problems, and severe leg pain).\(^4\)

Managing Oral Contraceptive Drug Interactions. The effectiveness of an OC is sometimes limited by drug interactions that interfere with gastrointestinal absorption, increase intestinal motility by altering gut bacteriologic flora, and alter the metabolism, excretion, or binding of the OC.\(^4\)\(^,\)\(^7\)\(^-\)\(^9\) The lower the dose of hormone in the OC, the greater the risk that a drug interaction will compromise its efficacy. Women should be instructed to use an additional method of contraception if there is a possibility of a drug interaction altering the efficacy of the OC.\(^4\) Although less well documented, these recommendations generally also apply to patients receiving transdermal and vaginal CHC products.

Of all antibiotics, rifampin is the one with a true documented pharmacokinetic interaction. Pharmacokinetic studies of other antibiotics have not shown any consistent interaction, but case reports of individual patients have shown a reduction in EE levels when OCs are taken with tetracyclines and penicillin derivatives.\(^3\)\(^1\)\(^2\) The ACOG states that ampicillin, doxycycline, fluconaolose, metronidazole, miconazole, fluoroquinolones, and tetracyclines do not decrease steroid levels in women taking OCs.\(^7\) The Council on Scientific Affairs at the American Medical Association recommends that women taking rifampin should be counseled about the risk of OC failure and advised to use an additional nonhormonal contraceptive agent during the course of rifampin therapy. The council also recommends that women be informed about the small risk of interactions with other antibiotics, and, if desired, appropriate additional nonhormonal contraceptive agents should be considered. In addition, women who develop breakthrough bleeding during concomitant use of antibiotics and OCs (and other CHCs) should be advised to use an alternate method of contraception during the period of concomitant use.\(^1\)\(^1\)

Women receiving certain anticonvulsants for a seizure disorder should be offered another form of contraception such as IUDs, injectable medroxyprogesterone, implants or nonhormonal options. Some anticonvulsants (mainly phenobarbital, carbamazepine, phenytoin) induce the metabolism of estrogen and progestin, inducing breakthrough bleeding and potentially reducing contraceptive efficacy. In addition, some anticonvulsants (e.g., phenytoin) are known teratogens.

Patient Instructions with Oral Contraceptives. Many women who take OCs are not educated properly on the appropriate use of these medications. Women should be given the package insert that accompanies all estrogen products and instructed to read it. The written patient information should be supplemented with verbal information describing the mechanism of the medication, both common and serious side effects and management of these side effects. Although several transient self-limiting side effects often occur, the patient should be aware of the danger signals that require immediate medical attention (Table 88–5). The benefits and risks should be discussed, including the fact that OCs provide no physical barrier to the transmission of STDs, including HIV. Detailed instructions on when to start taking the OC should be provided. Patients should be told the importance of routine daily administration to ensure consistent plasma concentrations and improve adherence and specific instructions should be given regarding what to do if a tablet is missed. The World Health Organization’s Selected Practice Recommendations for Contraceptive Use was updated recently with regard to missed oral contraceptives.\(^3\)\(^5\) In addition to when the tablet(s) is missed and how many are missed, the guidelines take into consideration whether the OC contains less than 30 mcg of EE. Limited evidence suggests that the risk of pregnancy is greater when 20 mcg tablets are missed than when 30 to 35 mcg tablets are missed. For instance, if a woman is taking a tablet containing 20 mcg EE and misses one dose or starts a pack 1 day late, she should take a tablet as soon as possible (two tablets on the same day) and then continue taking the rest of the tablets daily. No additional contraceptive protection is necessary. If, however, two or more tablets are missed or the pack is started 2 or more days late, the woman should follow the same instructions, but condoms should be used or she should abstain from sexual intercourse until she has taken active tablets for 7 days in a row. If missed tablets occur in the third week, she should finish the active tablets in the current pack and start a new pack the next day. She should not take the 7 inactive tablets. If the missed doses occur in the first week and unprotected intercourse has occurred, she should consider the use of emergency contraception. Instructions are similar for the 30 to 35 mcg tablets; however, no additional contraceptive protection is necessary unless three or more active tablets are missed or the woman starts a pack 3 or more days late. It should be noted that the

Data from Hatcher and Nelson,\(^4\) and Dickey.\(^1\)
Society of Obstetricians and Gynecologists of Canada also recently published guidelines in 2008 for missed doses. These guidelines differ slightly and do not account for the estrogen content of the tablet. Instructions also may vary in package inserts, which can make for increased confusion with patients and providers. It may be prudent, when differing instructions exist, to recommend the more conservative approach when dealing with individual patient situations.

**Discontinuing Oral Contraceptives and Return of Fertility.**

The ACOG states that there is no evidence that OC use decreases subsequent fertility. The transdermal patch and vaginal ring CHCs also have similar effects on fertility. The average delay in ovulation after discontinuing OCs is 1 to 2 weeks; however, delayed ovulation is more common in women with a history of irregular menses. If amenorrhea does continue beyond 6 months, women should be counseled to see a gynecologist for further fertility workup. Traditionally, women are counseled to allow two to three normal menstrual periods before becoming pregnant to permit the reestablishment of menstrual and ovulation. However, in several large cohort and case-control studies, infants conceived in the first month after discontinuation of an OC had no greater chance of miscarriage or being born with a birth defect than those born in the general population.

**Transdermal Contraceptives**

A CHC is available as a transdermal patch (Ortho Evra), which includes 0.75 mg of EE and 6 mg of norelgestromin, the active metabolite of norgestimate. Comparative trials have shown the transdermal patch to be as effective as combined OCs in patients weighing less than 90 kg (198 lbs). Of the 15 pregnancies reported in the clinical trials, five were among women weighing more than 90 kg (198 lbs); therefore, this product is not recommended as a first-line option for these women. Some patients experience application-site reactions, but other side effects are similar to those experienced with OCs (e.g., breast discomfort, headache, and nausea). A warning from the manufacturer states that women using the patch are exposed to approximately 60% more estrogen than from a typical OC containing 35 mcg of EE, but the mechanism is unclear. It is clear that there is increased estrogen exposure, but controversy exists correlating the increased exposure to increased risk of VTE, cardiovascular, and cerebrovascular events. Two epidemiologic studies present conflicting results. One trial indicates a higher incidence of VTE with the patch compared with a typical OC, whereas the other trial indicates there is no significant difference. Currently, the U.S. Food and Drug Administration (FDA) is monitoring this risk because more consistent data are needed. The patch should be applied to the abdomen, buttocks, lower back, upper torso, or upper arm at the beginning of the menstrual cycle and replaced every week for 3 weeks (the fourth week is patch free). The patch releases estrogen and progestin for 9 days. If the woman forgets to change her patch or restarts the active patches after the ninth day, a backup method should be used for 7 days. Approximately 5% of patches will need to be replaced because they become partly detached or fall off altogether, so single replacements are available. If the patch is detached for more than 24 hours, a new 4-week cycle should be started and a backup method used for 7 days. Users have demonstrated greater adherence with the patch than with an OC, but whether this results in reduced pregnancy rates remains to be seen. The benefits of adherence must be weighed against the risk of increased estrogen exposure and possibility of VTE.

**Vaginal Rings**

It is a 54-mm flexible ring, 4 mm in thickness. Over a 3-week period, the ring releases approximately 15 mcg/day of EE and 120 mcg/day of etonogestrel. Comparative trials have shown the vaginal ring to be as effective as combined OCs. On the first cycle of use, the ring should be inserted on or before the fifth day of the menstrual cycle, remain in place for 3 weeks, then removed for 1 week to allow for withdrawal bleeding. The new ring should be inserted on the same day of the week as it was during the last cycle, similar to starting a new OC pack on the same day of the week. A second method of contraception should be used if the ring has been expelled accidentally for more than 3 hours; if less than 3 hours, it should be washed and reinserted. Side effects, precautions, and contraindications for use of the hormonal ring are similar to those for all CHCs. The most commonly reported reasons for discontinuation of use were device-related issues, such as foreign-body sensation, device expulsion, and vaginal symptoms. Cycle control with the vaginal ring appears to be equal or better than combined OCs, with a low incidence of breakthrough bleeding and spotting after the second cycle of use, presumably due to increased adherence and release of steady levels of estrogen and progestin. Patient acceptability of the delivery system has been studied, and the majority of women do not complain of discomfort in general or during intercourse. A potential concern is the possibility of increased VTE since etonogestrel, is a metabolite of desogestrel which may be associated with increased risk. A few cases of VTE have been reported in clinical trials, but currently there are no published data to support this concern.

The ring should be inserted vaginally. In contrast to diaphragms and cervical caps, precise placement is not an issue because the hormones are absorbed anywhere in the vagina. Women should be in a comfortable position, and compress the ring between the thumb and index finger and push it into the vagina. There is no danger of inserting the ring too far because the cervix will prevent it from traveling up the genital tract. Removal of the ring is performed in a similar manner; pulling it out and discarding into the foil patch (the ring should not be flushed down the toilet). Patients should be discouraged from douching, but other vaginal products, including antifungal creams and spermicides, can be used.

**Long-Acting Injectable and Implantable Contraceptives**

Steroid hormones provide long-term contraception when injected or implanted into the skin. Progestins are used in existing injectable and implantable contraceptives. Sustained progestin exposure blocks the LH surge, thus inhibiting ovulation. Should ovulation occur, progestins reduce ovum motility in the fallopian tubes. Even if fertilization occurs, progestins thin the endometrium, reducing the chance of implantation. Progestins also thicken the cervical mucus, producing a barrier to sperm penetration. These long-acting methods of contraception do not provide any protection from STDs.

Women who particularly benefit from progestin-only methods are those who are breast-feeding, those who are intolerant to estrogens (i.e., have a history of estrogen-related headache, breast tenderness, or nausea) or those with concomitant medical conditions in which estrogen is not recommended. Additionally, injectable and implantable contraceptives are beneficial for women with adherence issues. Pregnancy failure rates with long-acting progestin contraceptives are comparable to the rates with female sterilization. Reports have stated an increased risk of ectopic pregnancies while using progestin-only methods, but no evidence supports this finding with use of the more recent injectable and implantable products.

**Injectable Progestins.**

Methoxyprogesterone acetate is similar in structure to naturally occurring progesterone. DMPA (Depo-Provera) is administered every 3 months either by deep intramuscular injection in the gluteal or deltoid muscle or subcutaneously in the abdomen or thigh within 5 days of onset of menstrual bleeding. With perfect use, the efficacy of DMPA is more than 99%; however, with typical use, 3% of women experience unintended pregnancy. Although these injections may inhibit ovulation for up to 14 weeks, the dose should be repeated every 3 months (12 weeks) to ensure continuous contraception. The manufacturer recommends excluding pregnancy in women with a lapse of 13 or
more weeks between injections for the intramuscular formulation or 14 or more weeks between injections for the subcutaneous formulation. Depo-Provera is available as a 150 mg/mL injection vial or prefilled syringe for IM injection and Depo-SubQ Provera 104 is available as a prefilled syringe. 

Although no adverse effects have been documented in infants exposed to DMPA through breast milk, the manufacturer recommends not initiating DMPA until 6 weeks postpartum in breastfeeding women. Women who are not breastfeeding but require contraception can receive DMPA immediately postpartum. Women with sickle cell disease are good candidates for DMPA, as studies have demonstrated a reduction in sickle cell pain crises in women using DMPA. In addition, women with seizure disorders may experience fewer seizures when taking DMPA for contraception. The subcutaneous DMPA formulation is FDA approved for treatment of endometriosis-associated pain. The incidence of Candida vulvovaginitis, ectopic pregnancy, and pelvic inflammatory disease, as well as endometrial and ovarian cancer, is decreased in women using DMPA for contraception compared with women using no contraception.

Because return of fertility may be delayed after discontinuation of DMPA, it should not be recommended to women desiring pregnancy in the near future. The median time to conception from the first omitted dose is 10 months. Sixty-eight percent of women will be able to conceive within 12 months, 83% within 15 months, and 93% within 18 months of the last injection.

Menstrual irregularities are the most frequent adverse effects of both formulations of DMPA. In some cases, bleeding is severe enough to cause a significant drop in hemoglobin. Women who cannot tolerate prolonged bleeding may benefit from a short course of estrogen (e.g., 7 days of 2 mg estradiol or 1.25-mg conjugated estrogen given orally). The incidence of irregular bleeding decreases from 30% in the first year to 10% thereafter. After 12 months of therapy, 55% of women report amenorrhea, with the incidence increasing to 68% after 2 years. However, bleeding patterns beyond 1 year of use have not been established for the subcutaneous formulation.

Other adverse effects, including breast tenderness, weight gain, and depression occur less commonly (less than 5%). However, weight gain averages 1 kg (2.2 lbs) annually and may not resolve until 6 to 8 months after the last injection. DMPA has been associated with short-term bone loss in younger women of reproductive age. This potential side effect may be due to lower ovarian estrogen production that occurs when gonadotropin secretion is suppressed. Longitudinal studies of women over the age of 18 have shown significant declines in hip and/or spinal BMD when used for up to 2 years compared with those who did not use the medication. This effect appears to be partially reversible after discontinuation of treatment, and no studies have found evidence of osteoporosis or fractures in these users. The largest longitudinal study of adult women in the United States found that within 30 months following DMPA discontinuation, BMD of the spine and hip was similar to that of nonusers. There is evidence from cross-sectional studies, however, to suggest that use of DMPA during adolescence before peak bone mass is achieved is detrimental in high-risk patients. Decreases in lumbar spine BMD of 1.5% and 3.1% in DMPA users after 1 and 2 years of use respectively have been demonstrated, compared with a 2.9% and 9.5% increase in controls over the same time periods. Because of these demonstrated effects on BMD, the FDA issued a black box warning for DMPA in 2004. It states that DMPA should be continued for more than 2 years only if other contraceptive methods are inadequate. It also states that this loss seems to be greater with increasing duration of use and may not be completely reversible. Ultimately, it is unclear whether use of DMPA during adolescence or early adulthood will increase the risk of fracture later in life or prevent them from achieving normal peak bone mass. What is clear is that clinicians should counsel patients on the benefits versus the risks of the medication and to make recommendations based upon available evidence. Patients should be encouraged to have an adequate daily intake of calcium and vitamin D and to exercise daily. Although controversial, some clinicians are recommending evaluations of BMD for those women on DMPA for greater than 2 years. However, ACOG does not currently recommend monitoring BMD solely in response to DMPA use. This recommendation is based upon the fact that any observed short-term loss in BMD associated with DMPA use may be recovered and is unlikely to place a woman at risk of fracture during use or in later years.

**Subdermal Progestin Implants.** Implanon is a single 4-cm-long implant, containing 68 mg of etonogestrel, that is placed under the skin of the upper arm using a preloaded inserter. Implanon releases etonogestrel at a rate of 60 mcg daily for the first month, then decreases to an average of 30 mcg daily at the end of the 3 years of recommended use. Etonogestrel suppresses ovulation in 97% of cycles. When ovulation is not suppressed, etonogestrel still is effective as the progestin thickens the cervical mucus and produces an atrophic endometrium. With perfect use, efficacy approaches 100% but may be reduced in women weighing more than 130% of their ideal body weight. Because only one rod is used, the difficulties experienced with insertion and removal hopefully will be avoided.

The etonogestrel implant should be inserted between days 1 and 5 of the menstrual cycle in women who have not previously used hormonal contraception. Women currently taking OCs can have the implant inserted within 7 days after taking the last active OC tablet. Women currently taking progestin-only oral contraceptives should have the implant inserted without skipping any days, on the same day that the progestin-only IUD is removed, or on the day that the DMPA injection is due. After removal, fertility returns within 30 days.

The major adverse effect associated with Implanon is irregular menstrual bleeding, which led to discontinuation of the implant in 11% of patients in clinical trials. Like the bleeding pattern seen with other progestins, some women (22%) became amenorrheic with continued use, but many continued to have prolonged bleeding and spotting (18%) and frequent bleeding (7%). Other adverse effects include headache, vaginitis, weight gain, acne, and breast and abdominal pain. The role of the progestin implant’s influence on BMD has become an area of controversy since the FDA required an inclusion of a black box warning for DMPA. In theory, the etonogestrel implant system should not decrease BMD as much as DMPA because estrogen concentrations are not as consistently suppressed. Clinical trials have demonstrated no significant relationship between use of the hormonal implant and changes in BMD. In addition, there are no long-term data and no data demonstrating a correlation between the implant and fracture risk or an increase in osteoporosis.

Implanon is a single implantable contraceptive agent that provides enhanced adherence and prolonged efficacy. Therefore, it may be a good choice for women with a history of non-adherence, those who do not plan to have children for at least 3 years or those who have estrogen-related adverse effects or contraindications. Because fertility returns quickly after removal and Implanon does not affect bone health, it may be preferred over DMPA. Women should be counseled about the risk of irregular bleeding patterns so that patients will not request early removal of Implanon.

**Intrauterine Devices**

The low-grade intrauterine inflammation and increased prostaglandin formation caused by IUDs and endometrial suppression caused specifically by the progestin-releasing IUD appear to be
primarily spermicidal, although interference with implantation is a backup mechanism. Efficacy rates with IUDs are greater than 99% with both perfect and typical use.\(^3,4,5,6,7\) Although they are a very effective form of contraception and are increasing in popularity, the IUD still has several contraindications. Patients who should be excluded from use of IUDs include: current pregnancy, pelvic inflammatory disease (current or within past 3 months), STD (current), puerperal or postabortion sepsis, purulent cervicitis, undiagnosed abnormal vaginal bleeding, malignancy of genital tract, uterine anomalies or fibroids distorting uterine cavity, allergy to IUD component, Wilson’s disease (for copper IUD). The risk of pelvic inflammatory disease among IUD users ranges from 1% to 2.5%. Because the increased risk of infection appears to be related to introduction of bacteria into the genital tract during IUD insertion, the risk is highest during the first 20 days after the procedure.\(^3,5,7\) Two IUDs currently are marketed in the United States; all are T-shaped and are medicated, one with copper (ParaGard) and one with levonorgestrel (Mirena).\(^3,4\)

ParaGard provides better contraceptive effectiveness than previous copper devices and can be left in place for 10 years.\(^3\) A disadvantage of ParaGard is increased menstrual blood flow and dysmenorrhea; average monthly blood loss among users increased by 35% in clinical trials. Mirena was released in the United States in 2001 and is becoming more widely used. It releases 20 mcg of levonorgestrel daily, but release decreases to 10 mcg daily over the 5 years of use.\(^3,4,5,7\) Systemically absorbed levonorgestrel is minimal and considerably less than with OCs. The levonorgestrel IUD produces its effects locally via suppression of the endometrium, causing a reduction in menstrual blood loss. In contrast to the copper IUD, menstrual flow in users of the levonorgestrel IUD is decreased, and development of amenorrhea has been observed in 20% of users in the first year and 60% in the fifth year. A disadvantage of the levonorgestrel IUD is increased spotting in the first 6 months of use; women should be counseled that the spotting will decline gradually over time.\(^3,4,5,7\)

IUDs should be considered because adherence is not an issue once inserted and result in immediate return of fertility once removed. The levonorgestrel IUD has many noncontraceptive benefits, specifically, it is a good choice for women with menorrhagia or dysmenorrhea because it reduces and may eliminate menstrual blood loss. IUDs, in general, are an alternative for women who cannot tolerate or have contraindications to estrogen-containing contraceptive agents. Recently, use in the adolescent and nulliparous population has been recommended in a select group of appropriate candidates due to the high contraceptive efficacy rate. It is important to adhere to the IUD contraindications and provide appropriate counseling to this population. Data to support wide use of this practice in this population are limited.\(^3\)

**Emergency Contraception**

EC is used to prevent unwanted pregnancy after unprotected sexual intercourse, including condom breakage, diaphragm dislodging, or sexual assault. Higher doses of combined estrogen and progestin or progestin-only containing products can be used.\(^1,3,5\) Insertion of copper IUD is an option, although it is not an FDA approved or a widely used method of EC. Currently, a progestin-only formulation containing levonorgestrel (currently marketed as Plan B, Plan B One-Step, Next Choice) is approved specifically for EC in the United States.\(^5,3,4,5,6\) Exact mechanisms of action of oral EC are being studied and vary according to the product used and the time a woman takes it in relation to her menstrual cycle.

Recent studies support that the primary mechanism of action of Plan B is inhibiting or delaying ovulation. Additional evidence suggests it may impair sperm transport and corpus luteum function, therefore inhibiting fertilization. The most recent data does not support that it may prevent the fertilized egg from implanting into the endometrium. Further research is ongoing in this area.\(^3,4,5,6,7\)

Pregnancy occurs when the fertilized egg is implanted into the endometrium. After intercourse, implantation of the fertilized egg typically takes approximately 5 days. Oral EC will not disrupt the fertilized egg after implantation has occurred.\(^3,4,5,6\) The levonorgestrel-containing EC formulation is the regimen of choice due to availability, improved tolerability, and potentially increased efficacy rates. Plan B and Next Choice contain two tablets, each containing 0.75 mg of levonorgestrel. The first dose is taken within 72 hours of unprotected intercourse (although the sooner, the more effective); the second dose is taken 12 hours later.\(^3,4,5,7\) One study found that 1.5 mg of levonorgestrel (two tablets of Plan B) taken as a single dose was as effective as taking the doses 12 hours apart and did not cause an increased incidence of adverse effects.\(^3,4,5,7\) Due to this evidence, a new formulation (Plan B One-Step) containing 1 tablet of 1.5 mg of levonorgestrel taken within 72 hours of unprotected intercourse is currently being marketed and the older Plan B may be phased out.\(^3,4,5,6\) Plan B was approved by the FDA in 2006 for OTC sales, as of 2009 it may be sold without a prescription to patients 17 years of age and older. It is sold only in pharmacies and must be stocked behind the counter. Patients must provide proof of age prior to purchasing the product. The manufacturer is continuing its efforts in gaining OTC status for increased provision to minors.\(^9\)

Despite the availability of progestin-only EC formulations, use of regular combined contraceptives for EC (i.e., Yuzpe method) still is permissible, although some studies suggest that they may not be as effective and may be associated with more adverse effects.\(^3,4,5,6\) Specifically, the FDA has declared the following regimens containing the progestins norgestrel and levonorgestrel safe and effective methods of EC: Ovral and Ogestrel (two tablets per dose); Nordette, Levlen, Levora, Lo/Ovral, Low-Ogestrel, Cryselle, Jolessa, Enpresse, Portia, Seasonale, Seasonique, Triphasil, TriLeven, or Trivora (four tablets per dose); and Alesse, Aviane, Lessina, Levlute, or Lutera (five tablets per dose).\(^3,4,5,6\) Additionally, regular progestin-only oral contraceptives can be used as EC, but many tablets must be taken (i.e., Ovrette, 20 tablets per dose).\(^3,4,5,6\) Patients should be counseled to take the appropriate number of tablets as soon as possible after unprotected sexual intercourse and to repeat the dose in 12 hours. Taking all the tablets at once as a single dose is not recommended when using combination oral contraceptives.

The efficacy of all EC regimens is improved when taken as soon as possible after unprotected intercourse (within the first 24 hours). EC is still effective when taken within 72 hours but begins to decline once that timeframe has elapsed.\(^3,4,5,6\) However, one study suggests that EC may still be effective when used up to 120 hours after intercourse and should be considered in some women when use is delayed.\(^3,4,5,6\) Determining the exact effectiveness rate is difficult;
however, the range has been reported to be between 59% and 94%. A meta-analysis of the literature has reported that EC may prevent an average of 75% of expected pregnancies when taken appropriately. It is recommended that women have an advanced prescription on hand or access to an OTC formulation to maximize the effectiveness of EC.1,2,3,4

Common adverse effects include nausea, vomiting, and irregular bleeding. Nausea and vomiting occur significantly less when progesterin-only EC is administered. If the Yuzpe method is prescribed, antiemetics given 1 hour before the dose is taken may be warranted to prevent the increased amount of estrogen-induced gastrointestinal adverse effects. Many women will experience irregular bleeding regardless of which EC method is used, with the menstrual period usually occurring 1 week before or after the expected time. No current data regarding the safety of repeated use EC are available, but current consensus suggests the risks are low, and women can receive multiple regimens if warranted. Pharmacists and other healthcare providers have a key role in providing patient counseling regarding EC. Appropriate counseling should be provided regarding timing of the dose, common adverse effects, and use of a regular contraceptive method (backup barrier methods should be used after EC for at least 7 days).1,4

**CLINICAL CONTROVERSY**

Pharmacists who refuse to fill valid prescriptions for emergency contraception have been highly publicized in the media. Position statements published by the American Pharmaceutical Association and American College of Clinical Pharmacy support pharmacists’ rights to decline filling a valid prescription if doing so conflicts with moral, ethical, or religious beliefs. However, it is the pharmacists’ professional responsibility to refer the patient to another pharmacist who will fill the prescription in a timely, confidential, and nonjudgmental manner so that no harm is caused to the patient.

**PHARMACOECONOMIC CONSIDERATIONS**

About one third of all pregnancies in the United States are unintended.1 Not all unintended pregnancies are unwanted; many are just “mistimed.” The United States has a higher rate of induced abortions than most other industrialized western nations. Whatever method is used, preventing unintended pregnancy is highly cost-effective. With regard to the acquisition cost of reversible contraception, the most cost-effective barrier method is the male condom. However, reliable pharmacologic methods can also be cost-effective. Injectable, implantable, and IUD options may carry a higher initial cost but would be comparable or even less costly in the long run. OCs, the contraceptive patch, and the vaginal ring are actually the most expensive forms of reversible contraception yet are the most commonly utilized in this country. Overall, with regard to direct medical costs (e.g., method use, adverse effects, and unintended pregnancies) over 5 years, IUDs are the most cost-effective method of contraception, along with sterilization. All contraceptive options (barrier and pharmacologic) are more cost-effective than no method at all.1,4

**EVALUATION OF THERAPEUTIC OUTCOMES**

Patients should receive both verbal and written instructions on the chosen method of contraception. Follow-up appointments can increase adherence and provide opportunities to address other health maintenance issues (e.g., self-breast examination, Pap smears, human papillomavirus vaccines, STD risk).4

Annual blood pressure monitoring is recommended for all users of CHC. When a patient with a history of glucose intolerance or diabetes mellitus begins or discontinues the use of CHC, glucose levels must be monitored closely for deterioration of the condition. Contraceptive users should also receive annual (more frequent if they are at risk for STDs) cytologic screening as well as annual examination for clinical problems related to CHC (e.g., breakthrough bleeding, weight gain, acne).

Women using Implanon should be monitored annually for menstrual cycle disturbances, weight gain, local inflammation, or infection at the implant site, acne, breast tenderness, headaches, and hair loss. Women using DMPA should be asked at 3-month follow-up visits about weight gain, menstrual cycle disturbances, and STD risks. Patients taking DMPA should be weighed, undergo blood pressure checks, and receive annual examinations as indicated based upon the age of the patient. Women using IUDs should be asked at 1- to 3-month follow-up visits about IUD placement (checking for IUD strings to assure the IUD is still in the proper position), changes in menstrual bleeding patterns, and symptoms and protection against STDs. Providers should check for proper IUD positioning and symptoms of upper genital tract infection.

Choosing a contraceptive method most suited to the patient’s needs will reduce the chance of unintended pregnancy. A medical and sexual history and a thorough physical examination are essential when evaluating the various methods available. Understanding the risks and precautions associated with the methods available is essential for both patients and clinicians. Counseling about OTC availability of EC or advanced provision of EC prescription is warranted for all women of child-bearing age. Finally, providers should counsel women about healthy sexual practices and encourage use of male condoms in addition to other barrier or pharmacologic contraceptives when necessary to prevent STDs.

**ABBREVIATIONS**

ACOG: American College of Obstetrics and Gynecology

CHAPTER 88

Contraception

REFERENCES

KEY CONCEPTS

1. Unrecognized pregnancy is the most common cause of amenorrhea. A urine pregnancy test should be one of the first steps in evaluating this disorder.

2. For hypoestrogenic conditions associated with primary and secondary amenorrhea, estrogen (with a progestin) is provided.

3. Causes of menorrhagia are either systemic disorders or specific uterine abnormalities.

4. Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis for any woman presenting with heavy menses.

5. The reduction in menorrhagia-related blood loss with use of nonsteroidal antiinflammatory drugs and oral contraceptives is directly proportional to the amount of pretreatment blood loss.

6. Intrauterine devices (IUDs) are considered therapeutic options in a variety of menstruation-related disorders. Guidelines from the American College of Obstetricians and Gynecologists indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.

7. Anovulatory bleeding is the standard terminology used to describe bleeding from the uterine endometrium as a result of a dysfunctioning menstrual system, specifically excluding an anatomic lesion of the uterus.

8. Polycystic ovarian syndrome can present as a variety of menstruation disorders, including amenorrhea, menorrhagia, and anovulatory bleeding. Although its definition continues to evolve, it is generally considered a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction.

9. Metformin and thiazolidinedione use for anovulatory bleeding associated with PCOS is beneficial not only for anovulatory bleeding and fertility but also for improving glucose tolerance and other metabolic parameters that contribute to cardiovascular risk.

10. The selective serotonin reuptake inhibitors are first-line pharmacologic treatment options for premenstrual dysphoric disorder.

Problems related to the menstrual cycle are exceedingly common in women of reproductive age. This chapter discusses the most frequently encountered menstruation-related difficulties: amenorrhea, menorrhagia, anovulatory bleeding, dysmenorrhea, premenstrual syndrome (PMS), and premenstrual dysphoric disorder (PMDD). The need for effective treatments of these disorders stems from their impact on any or all of the following: a reduced quality of life, negative effects on reproductive health, and potential for long-term detrimental health effects, such as osteoporosis with amenorrhea and cardiovascular disease with polycystic ovary syndrome (PCOS).

AMENORRHEA

Amenorrhea is described as either primary or secondary in nature. Primary amenorrhea is the absence of menses by age 16 years in the presence of normal secondary sexual development or the absence of menses by age 14 in the absence of normal secondary sexual development. Secondary amenorrhea is the absence of menses for three cycles or for 6 months in a previously menstruating woman. There is a significant amount of overlap between the two. The initial evaluation of amenorrhea often is the same, regardless of age of onset, except in unusual clinical situations.

EPIDEMIOLOGY

Primary amenorrhea occurs in less than 0.1% of the general population. Secondary amenorrhea, in comparison, has an incidence of 0.7% to 5% in the general population and occurs more frequently in women younger than 25 years with a history of menstrual irregularities and in those involved in competitive athletics.

ETIOLOGY

1. Unrecognized pregnancy is the most common cause of amenorrhea. A urine pregnancy test should be one of the first steps in evaluating this disorder. In organizing an approach to diagnosis and treatment, it is helpful to consider the organs involved in the menstrual cycle, which include the uterus, ovaries, anterior pituitary, and hypothalamus.

After excluding pregnancy, the most common causes of secondary amenorrhea are hypothalamic suppression, chronic anovulation, hyperprolactinemia, ovarian failure, and uterine disorders.

PATHOPHYSIOLOGY

Each organ in the hypothalamic–pituitary–ovarian–uterine axis is of importance in determining amenorrhea’s etiology and pathophysiology. Beginning with the uterus/outflow tract and progressing caudally will result in a comprehensive differential diagnosis.
Table 89–1 lists the pathophysiology of amenorrhea relative to the organ system(s) involved and the specific condition(s) that results in amenorrhea.

### Uterus/Outflow Tract

For menstruation to occur, a uterus, functional endometrium, and patent vagina must be present. Several anatomic abnormalities may cause amenorrhea. If primary amenorrhea is the presenting symptom, a congenital anomaly such as imperforate hymen or uterine agenesis may be present and often discovered by physical examination. An acquired condition of the genital tract, such as Asherman syndrome or cervical stenosis, is more likely in secondary amenorrhea.

### Ovaries

Normal ovarian function is critical for menstruation to occur. The ovaries must respond appropriately to follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by secreting estrogen and progesterone in proper sequence to influence endometrial growth and shedding (Fig. 89–1).

Premature ovarian failure occurs when no viable follicles remain in the ovaries. This is because estrogen production is insufficient to stimulate endometrial growth in the absence of follicles. In a woman younger than 30 years, amenorrhea due to premature ovarian failure may be the result of genetic anomalies.

The ovaries may play a role in amenorrhea through anovulation. Ovulation is required for the follicle (an estrogen-secreting body) to become a corpus luteum (a progesterone-secreting body). Without ovulation, the proper sequence of estrogen production, progesterone production, and estrogen/progesterone withdrawal will not occur. This can result in amenorrhea. Anovulation can occur secondary to thyroid disease, androgen excess (PCOS), or chronic illness.
Pituitary Gland
The anterior pituitary gland secretes FSH and LH in sequential fashion in response to hypothalamic stimulation and a complex ovarian feedback mechanism. Normal secretion of FSH and LH is altered by several endocrinologic and iatrogenic conditions, including thyroid disease, hyperprolactinemia, and dopaminergic drug administration.

Hypothalamus
The hypothalamus secretes cyclic gonadotropin-releasing hormone (GnRH), which causes the pituitary to produce FSH and LH. Disrupting this cyclic excretion will interrupt the hormonal cascade that results in normal menstruation. Anorexia nervosa, bulimia, intense exercise, and stress may cause hypothalamic amenorrhea.

CLINICAL PRESENTATION OF AMENORRHEA

General
- Although patients may be concerned about cessation of menses and implications for fertility, patients are generally not in acute distress.

Symptoms
- Patient will note cessation of menses.
- Patients may complain of infertility, vaginal dryness, or decreased libido.

Signs
- Cessation of menses for more than 6 months in women with established menstruation, absence of menses by age 16 years in the presence of normal secondary sexual development, or absence of menses by age 14 years in the absence of normal secondary sexual development
- Recent significant weight loss or weight gain
- Presence of acne, hirsutism, hair loss, or acanthosis nigra
- Patients may suggest androgen excess

Laboratory Tests
- Pregnancy test
- Thyroid-stimulating hormone
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, fasting lipid panel
- If suspect premature ovarian failure, consider FSH, LH

Other Diagnostic Tests
- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

TREATMENT

The treatment options for amenorrhea are as varied as its causes.

Desired Outcome
Therapeutic modalities for amenorrhea should ensure the occurrence of normal puberty and restore the menstrual cycle. Treatment goals include bone density preservation, bone loss prevention, and ovulation restoration, improving fertility as desired. Amenorrhea from hypoestrogenism may affect quality of life via hot flash induction (premature ovarian failure), dyspareunia, and, in prepubertal females, lack of secondary sexual characteristics and absence of menarche. Treatment is targeted at reversing these effects.

General Approach to Treatment
The overall success of any intervention to treat amenorrhea is dependent on proper identification of the disorder’s underlying cause(s). Once the cause is identified, the appropriate intervention(s) can be made. For patients experiencing amenorrhea secondary to hypoestrogenic states, a diet rich in calcium and vitamin D is essential to avoid negative impact on bone health.

Nonpharmacologic Therapy
Nonpharmacologic therapy for amenorrhea varies depending on the underlying cause. Amenorrhea secondary to anorexia may respond to weight gain. In young women for whom excessive exercise is an underlying cause, reduction of exercise quantity and intensity are important.

Pharmacologic Therapy
- For hypoestrogenic conditions associated with primary or secondary amenorrhea, estrogen (with a progestin) is provided. It can be administered as an oral contraceptive (OC), conjugated equine estrogen, or estradiol patch. Estrogen therapy in this patient population reduces osteoporosis risk and improves quality of life. Table 89–2 lists therapeutic agents for amenorrhea treatment, including recommended doses. Figure 89–2 illustrates a treatment algorithm for management of amenorrhea.

Pharmacologic Therapy
- When hyperprolactinemia is the cause of amenorrhea, dopamine agonists, including bromocriptine and cabergoline aid in reducing prolactin concentrations and the resumption of menses. Bromocriptine requires multiple doses per day; cabergoline is dosed twice weekly. When compared with cabergoline, bromocriptine is less effective in normalizing prolactin levels and has a higher incidence of adverse events leading to treatment discontinuation.

Amenorrhea related to PCOS-induced anovulation may respond to agents that reduce insulin resistance. Metformin and the thiazolidinediones for this purpose are discussed in the anovulatory bleeding section.

Progestins induce withdrawal bleeding in women with secondary amenorrhea. Several factors predict progesterone's efficacy for this purpose. These factors include estrogen concentrations greater than or equal to 35 pg/mL (128 pmol/L) and endometrial thickness (greater initial thickness resulting in more withdrawal bleeding).

Progestin efficacy for secondary amenorrhea varies by formulation used. Progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate (MPA) induces withdrawal bleeding in 95% of treated patients. Table 89–2 identifies the types and doses of progestins used for secondary amenorrhea treatment. Figure 89–2 illustrates when to consider progestin use for amenorrhea treatment.

Special Populations Amenorrhea in the adolescent population is of concern because this is the developmental time when peak bone mass is achieved. The cause of amenorrhea, whether primary or secondary, must be promptly identified in this population, as amenorrhea and its related hypoestrogenism negatively affect bone development. In addition to treating or eliminating amenorrhea’s underlying cause, ensuring that the patient is receiving adequate amounts of calcium and vitamin D is imperative. Estrogen replacement, typically via an OC, is important.

Drug Class Information Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used for amenorrhea management.
Menorrhagia rates in healthy women range from 9% to 14%. IBMICROSOFT Word Document (PDF creation)

CHAPTER 89

TREATMENT

Initial treatment choice for menorrhagia is influenced by whether or not the woman desires to become pregnant.

Desired Outcome

Menorrhagia therapy should reduce menstrual blood flow, improve the patient’s quality of life, and defer the need for surgical intervention. Table 89–2 lists the agents and their recommended dosing for menorrhagia management. Figure 89–3 presents an algorithm for menorrhagia treatment.

PATHOPHYSIOLOGY

Table 89–1 lists the pathophysiology of menorrhagia relative to the organ system(s) involved and the specific conditions that result in menorrhagia.

FIGURE 89-2. Treatment algorithm for amenorrhea. *Regardless of cause, adequate calcium and vitamin D intake must be ensured. (OC, oral contraceptive; PCOS, polycystic ovary syndrome.)

CLINICAL PRESENTATION OF MENORRHAGIA

General

■ Patient may or may not be in acute distress.

Symptoms

■ Patients may complain of heavy/prolonged menstrual flow. They also may have signs of fatigue and lightheadedness in cases of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs

■ Orthostasis, tachycardia, and pallor may be noted, especially in cases of significant acute blood loss.

Laboratory Tests

■ Complete blood count and ferritin levels; hemoglobin and hematocrit results may be low.

■ If the history dictates, testing may be performed to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

■ Pelvic ultrasound

■ Pelvic magnetic resonance imaging

■ Papanicolaou (Pap) smear

■ Endometrial biopsy

■ Hysteroscopy

■ Sonohysterogram

TREATMENT

Initial treatment choice for menorrhagia is influenced by whether or not the woman desires to become pregnant.

Desired Outcome

Menorrhagia therapy should reduce menstrual blood flow, improve the patient’s quality of life, and defer the need for surgical intervention. Table 89–2 lists the agents and their recommended dosing for menorrhagia management. Figure 89–3 presents an algorithm for menorrhagia treatment.

General Approach to Treatment

Several treatment options exist for menorrhagia. Initial and subsequent treatment options should be thoughtfully chosen in an effort to avoid surgery.

Nonpharmacologic Therapy

Nonpharmacologic interventions for menorrhagia include surgical procedures that are generally reserved for patients not responding...

to pharmacologic treatment. These interventions vary from conservative endometrial ablation to hysterectomy. 15

**Pharmacologic Therapy**

Among the agents used to treat menorrhagia, the nonsteroidal antiinflammatory drugs (NSAIDs) have the advantage of administration only during menses. NSAID use is associated with a 20% to 50% reduction in menstrual blood loss in 75% of treated women. 15 In some patients, as much as an 80% reduction in blood loss has been observed. 15

For women desiring to avoid pregnancy, OC use is beneficial for menorrhagia and should be considered. A 43% to 53% reduction in menstrual blood loss has been observed in 68% of menorrhagia patients treated with OCs containing greater than or equal to 50% reduction in blood loss in 75% of treated women. 15 In particular, an 86% reduction in blood loss has been observed in 68% of treated women. 15

Another menorrhagia treatment option is the levonorgestrel-releasing intrauterine device (IUD). This is a very effective treatment that consistently reduces menstrual flow by at least 90%. 15,18 In particular, an 86% reduction in blood loss has been observed after 3 months of use; as much as 97% after 12 months. 19 Its use has also resulted in postponing or cancelling scheduled endometrial ablation surgery or hysterectomy. Sixty percent of treated patients avoided hysterectomy when employing this treatment option. 38,40,41 and its therapeutic efficacy is similar to endometrial ablation up to 2 years following treatment. 19

Progestosterone therapy either during the luteal phase of the menstrual cycle or for 21 days, starting on day 5 after onset of menses, results in a 32% to 50% reduction in menstrual blood loss. 15 However, progestosterone use is not superior to other medical treatments, including the NSAIDs. 15

Tranexamic acid was recently approved in the United States for primary menorrhagia treatment. Its use is associated with a significant 40% to 50% reduction in menstrual blood loss. 17

**Drug Treatments of First Choice**

For women who have menorrhagia associated with ovulatory cycles and do not desire hormonal therapy and/or contraception, NSAIDs during menses is a reasonable choice, in the absence of any contraindications or gastrointestinal illnesses such as peptic ulcer disease or gastroesophageal reflux disease. This choice is convenient (only taken during menses) and comparatively inexpensive. For women desiring contraception, it is reasonable to start with either an OC or the levonorgestrel-releasing IUD. Either choice is acceptable for both nulligravid and multiparous women who desire a long-term reversible form of contraception. 38 Given cost-effectiveness data, the levonorgestrel-releasing IUD is the best first-line choice for women desiring contraception. 41 Clinical trial data illustrate a higher failure rate with the OCs (62.5%) compared with the levonorgestrel-releasing IUD (34%) as the primary treatment method. 42
Alternative Drug Treatments  Given their side effects, reduced efficacy compared with the first-line agents, and/or cost, use of oral progesterone and depot MPA should be reserved. Tranexamic acid is another treatment option. In comparison to luteal phase oral progesterone, tranexamic acid results in a significantly greater reduction in menstrual blood loss and greater relief of patient-reported symptoms. Its use has been associated with a significant improvement in quality of life and high patient satisfaction following three cycles of use.15,20

Special Populations  Although historically it was believed that IUD use should be avoided in nulliparous women, the American College of Obstetricians and Gynecologists (ACOG) indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.38 Therefore, any of the treatments discussed are options in any female presenting with menorrhagia. Dosage adjustment for tranexamic acid is recommended for reduced renal function. Women with serum creatinine between 1.4 and 2.8 mg/dL (124 and 248 μmol/L) should receive only 1,300 mg by mouth twice daily; women with serum creatinine between 2.9 and 5.7 mg/dL (256 and 504 μmol/L) should receive 1,300 mg by mouth once daily; those with serum creatinine above 5.7 mg/dL (504 μmol/L) should receive 650 mg by mouth once daily.

Drug Class Information  Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents for menorrhagia management.

PHARMACOECONOMIC CONSIDERATIONS  The levonorgestrel-releasing IUD is the most cost-effective option when compared to surgical management and OCs in OC-naïve women and women who had received OCs with or without a response.42

EVALUATION OF THERAPEUTIC OUTCOMES  Table 89–4 illustrates the expected outcomes and specific monitoring parameters for the treatment modalities used in menorrhagia management.

ANOVULATORY BLEEDING  Anovulatory bleeding is the standard terminology used to describe bleeding from the uterine endometrium as a result of a dysfunctional menstrual system, specifically excluding an anatomic lesion of the uterus.12 Anovulatory bleeding is also referred to as dysfunctional or irregular uterine bleeding.

EPIDEMIOLOGY  Anovulatory bleeding is the most common form of noncyclic uterine bleeding.1 PCOS is the most common cause, with prevalence rates ranging from 5% to 10% in various reports, depending on the diagnostic criteria used (e.g., PCOS-NIH43 or PCOS-Rotterdam44).1,3,45,48 In fact, PCOS is the most common
endocrine abnormality among U.S. women of reproductive age. 23 PCOS can present as a variety of menstruation disorders, including amenorrhea, menorrhagia, and/or anovulatory bleeding. Although its exact definition continues to evolve, it is a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction. It is a significant risk factor for the metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and possibly cardiovascular disease. 22, 47, 48 PCOS is a common cause of ovulation dysfunction in adult women. 22 Other common causes in adult women include hyperprolactinemia, hypothalamic amenorrhea, also known as hypogonadotropic hypogonadism, premature ovarian failure, and thyroid dysfunction. 1, 32

ETIOLOGY

When considering the etiology of anovulatory bleeding, the patient’s age must be considered. All patients presenting with abnormal bleeding should be evaluated for pregnancy. Most adolescents will experience physiologic anovulatory cycles in the first few years following menarche because their hypothalamic–pituitary–gonadal axis is still maturing. However, if an adolescent has not developed regular menstrual cycles within 5 years of menarche, further evaluation for the cause, such as PCOS, should be considered. 49 Anovulatory cycles may “unmask” an underlying bleeding disorder. When irregular menses are associated with significant bleeding, an inherited bleeding disorder should be a considered cause, especially in adolescence. 6, 32 Women experiencing anovulation in their reproductive years should be evaluated for pathologic causes, including PCOS, thyroid dysfunction, hyperprolactinemia, primary pituitary disease, premature ovarian failure, hypothalamic dysfunction, disordered eating, adrenal disease, and androgen-producing tumors. Women in their perimenopausal years may experience “physiologic” anovulatory cycles because of intermittently declining estrogen levels. Regardless of age, evaluation for endometrial hyperplasia and/or endometrial cancer should be considered when a woman experiences excessive bleeding with anovulatory cycles. When considering the etiology of anovulation, it is common for several conditions to coexist (e.g., PCOS and hypothyroidism), each contributing to the woman’s constellation of symptoms. All common etiologies should be considered when beginning to evaluate anovulation. 1

PATHOPHYSIOLOGY

Normal menstrual cycles occur through a complex interaction of the hypothalamus, pituitary gland, ovaries, and endometrium (Fig. 89–1). In an ovulatory cycle, the ovary produces a mature, estrogen-secreting follicle in response to FSH release from the pituitary. The endometrium proliferates under the influence of this estrogen production. At a critical level of estrogen concentration, the pituitary responds by producing an “LH surge,” which creates a cascade of ovarian events, culminating in ovulation. Upon oocyte release, the follicle becomes a progesterone-producing corpus luteum. The endometrium “organizes” into secretory endometrium in the presence of adequate progesterone. If conception and implantation do not occur, corpus luteum involution causes a decline in estrogen and progesterone leading to predictable, organized menstrual flow as the endometrium sloughs. If ovulation does not occur, progesterone is not produced, and the endometrium will continue to proliferate in an “unorganized” fashion under the influence of continued estrogen production. Eventually the endometrium will become so thick that it can no longer be supported by continued estrogen production. This results in unorganized, sporadic sloughing of the endometrium, characteristic of the unpredictable and heavy bleeding of anovulation. Anovulation has several etiologies. In adolescence, hypothalamic–pituitary axis immaturity contributes to the absence of the LH surge required for ovulation. In the anorexic patient, the hypothalamus loses much of its pulsatile GnRH release, leading to low levels of FSH and LH, enough for estrogen production but not enough to induce ovulation.

CLINICAL PRESENTATION OF ANOVULATORY BLEEDING

General
- Patients may or may not be in acute distress.

Symptoms
- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, night sweats, vaginal dryness)

Signs
- Acne, hirsutism, obesity

Laboratory Tests
- If PCOS is suspected, consider free or total testosterone fasting glucose, fasting lipid panel
- If perimenopause is suspected, measure FSH
- Thyroid-stimulating hormone

Other Diagnostic Tests
- If the patient is older than 35 years, endometrial biopsy
- Pelvic ultrasound to evaluate for polycystic ovaries
- If perimenopause is suspected, measure FSH

TREATMENT

Optimizing anovulatory bleeding therapy depends on accurate identification of the disorder’s cause(s). The treatment options for anovulatory bleeding are wide and varied.

Desired Outcome
Control of excessive bleeding in the short-term is paramount. Longer-term goals of therapy include restoring the natural cycle of orderly endometrial growth and shedding, 32, 56 decreasing anovulation complications (e.g., osteopenia, infertility), and improving overall quality of life. Table 89–2 identifies the agents used to manage anovulatory bleeding and their recommended doses.

General Approach to Treatment
Although the appropriate primary treatment choice for anovulatory bleeding depends on the accurate diagnosis of its cause and identification of desired outcomes, additional treatment may be necessary to manage other signs and symptoms. Treatment to resolve anovulatory bleeding should be initiated and any underlying menorrhagia should be managed.

Nonpharmacologic Therapy
Nonpharmacologic treatment options for anovulatory bleeding depend on the underlying cause. In a woman of reproductive age with PCOS, weight loss may be beneficial. 22 In women who have completed childbearing or who have not responded to medical management, endometrial ablation or resection and hysterectomy are surgical options. Procedure choice involves shared decision making with the patient. In the short term, ablation results in less morbidity and shorter recovery periods. However, a significant number of women eventually undergo hysterectomy in the subsequent 5 years. 32
Pharmacologic Therapy

Estrogen is the recommended treatment for managing acute severe bleeding episodes because it promotes endometrial stabilization. Following its initial use to control acute bleeding episodes, therapy continuation may be necessary to prevent future occurrences. OC use fulfills this role and contributes to predictable menstrual cycles.

OCs prevent recurrent anovulatory bleeding by providing a progestin and suppressing ovarian hormones and adrenal androgen production. They also, indirectly, increase sex hormone-binding globulin (SHBG). SHBG binds androgens and reduces their circulating free concentrations. For women with high androgen levels and its related signs such as hirsutism (e.g., those with PCOS), OCs containing less than or equal to 35 mcg of ethinyl estradiol and a progesterone that exhibits minimal androgenic side effects (e.g., norgestimate and desogestrel) or with antiandrogenic effects (e.g., drospirenone) may be desirable.

In women with contraindication(s) to estrogen or in whom the side effects are unacceptable, progesterone-only products are an option. They should be strongly considered for women experiencing menorrhagia associated with anovulatory bleeding. In women with PCOS, depot and intermittent oral MPA provide endometrial protection through endometrial shedding. If pregnancy is not a desired outcome of treatment, another progesterone option is placement of a levonorgestrel-containing IUD.

Metformin and the thiazolidinediones, including pioglitazone and rosiglitazone, improve insulin sensitivity. In patients with PCOS, this contributes to reduced circulating androgen concentrations, increased ovulation rates, and improved glucose tolerance. These improvements occur due to the SHBG increase that occurs via increased insulin sensitivity. Metformin and thiazolidinedione use for anovulatory bleeding associated with PCOS is beneficial not only for anovulatory bleeding and fertility but also for improving glucose tolerance and other metabolic parameters that contribute to cardiovascular risk. For women desiring pregnancy, metformin is pregnancy category B, and pioglitazone and rosiglitazone are category C.

Drug Treatments of First Choice

As with many menstruation-related disorders, there is not one universal treatment option of first choice for anovulatory bleeding. Rather, the treatment(s) chosen depends on accurate etiologic diagnosis as well as identification of the desired treatment outcome(s).

OCs are the first-choice treatment in women with anovulatory bleeding. While controversial, the use of OCs containing ethinyl estradiol and a progesterone with minimal androgenic or antiandrogenic effects is effective for cycle control and minimizing the androgenic signs and symptoms of PCOS.

Relative to anovulation in women with PCOS, insulin-sensitizing agents, including metformin and the thiazolidinediones, improve ovulatory frequency and metabolic parameters. Clomiphene use may further assist in achieving ovulation induction.

More recent data supports even further the use of metformin compared with clomiphene for ovulation induction as well as its use throughout pregnancy in women with PCOS has been associated with reduced miscarriage rates in this patient population.

Special Populations

Anovulatory cycles are fairly common in the perimenarcheal reproductive years. Ovulation typically is established 1 year or more following menarche. Anovulatory bleeding occurring in this population may be excessive. If excessive bleeding occurs, the patient should be evaluated for bleeding disorders. The prevalence of bleeding disorders, including von Willebrand disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura, in this population ranges from 5% to 24%.

If identified, the specific bleeding disorders should be treated. Acute severe bleeding can be managed with high-dose estrogen. OCs containing less than or equal to 35 mcg of ethinyl estradiol is a first-line treatment in adolescents with chronic anovulation.

Drug Class Information

Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of agents used to treat anovulatory bleeding.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used to manage anovulatory bleeding.

DYSMENORRHEA

Dysmenorrhea is one of the most commonly encountered gynecologic complaints. It is defined as crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the
setting of normal pelvic anatomy and physiology. Secondary dysmenorrhea is associated with underlying pelvic pathology.\textsuperscript{14}

**EPIDEMIOLOGY**

Dysmenorrhea prevalence rates range from 16% to 90%.\textsuperscript{33,34} Its presence may be associated with significant interference in work and school attendance. Risk factors include young age, heavy menses, nulliparity, early menarche, and cigarette smoking.\textsuperscript{9,12}

**ETIOLOGY**

For most patients, dysmenorrhea is associated with normal ovulatory cycles and normal pelvic anatomy. This is referred to as primary, or functional, dysmenorrhea. However, in approximately 10% of the adolescents and young adults presenting with painful menses, an underlying anatomic or physiologic cause exists.\textsuperscript{12}

**PATHOPHYSIOLOGY**

The most significant mechanism for primary dysmenorrhea is the release of prostaglandins and leukotrienes into the menstrual fluid, initiating an inflammatory response and possibly vasopressin-mediated vasoconstriction.\textsuperscript{9,12,29} Causes of secondary dysmenorrhea include cervical stenosis, endometriosis, pelvic infections, pelvic congestion syndrome, uterine or cervical polyps, uterine fibroids, genital outflow tract obstructions, and pelvic adhesions.\textsuperscript{12,34} Pregnancy and miscarriage must be considered in the presentation of dysmenorrhea.

**CLINICAL PRESENTATION OF DYSMENORRHEA**

**General**

- Patient may or may not be in acute distress, depending on the level of menstrual pain experienced.

**Symptoms**

- Patients complain of crampy pelvic pain beginning shortly before or at the onset of menses. Symptoms typically last from 1 to 3 days.

**Laboratory Tests**

- Pelvic examination should be performed to screen for sexually transmitted diseases as a cause of the pain in sexually active females.
- Gonorrhea, *Chlamydia* cultures or polymerase chain reaction, wet mount

**Other Diagnostic Tests**

- Pelvic ultrasound can be used to identify potential anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

**TREATMENT**

Initial treatment choice is influenced by whether or not the woman desires pregnancy. Nonpharmacologic options have been studied and observed to be as effective as some existing pharmacologic options.

**Desired Outcome**

Medical management of dysmenorrhea should relieve the pelvic pain and result in reducing lost school and work days. Table 89–2 identifies the agents used to manage dysmenorrhea and their recommended doses. Figure 89–4 shows a treatment algorithm for dysmenorrhea management.

**General Approach to Treatment**

A variety of effective treatment options for dysmenorrhea are available, including nonhormonal and hormonal pharmacologic options and noninvasive nonpharmacologic options. Treatment choice is influenced by the desire for contraception, the patient’s level of sexual activity, potential for adverse effects, and cost.

**Nonpharmacologic Therapy**

Several nonpharmacologic interventions are used for managing dysmenorrhea. Among these, topical heat therapy, exercise, and a low-fat vegetarian diet have been shown to reduce dysmenorrhea intensity.\textsuperscript{12,13,14,33} Dietary changes may shorten dysmenorrhea duration. Topical heat application via an abdominal patch worn for 12 consecutive hours/day is as effective as 400 mg of ibuprofen dosed 3 times daily.\textsuperscript{56} Because topical heat, exercise, and dietary changes do not impart systemic effects, they are associated with little to no risk compared to the pharmacologic options. Nonpharmacologic options that are reserved for use following a failed trial of pharmacologic interventions include transcutaneous electric nerve stimulation, acupressure, and acupuncture.\textsuperscript{34,33}

**Pharmacologic Therapy**

Given the role of prostaglandins in dysmenorrhea pathophysiology, NSAIDs are the initial treatment of choice. These agents do not differ in efficacy. The most commonly used agents are naproxen and ibuprofen.

![Figure 89-4. Treatment algorithm for dysmenorrhea. (IUD, intrauterine device; MPA, medroxyprogesterone acetate; NSAIDs, nonsteroidal antiinflammatory drugs; OC, oral contraceptive.)](image-url)
All NSAIDs have a propensity for causing gastrointestinal distress and ulceration; their administration with food or milk minimizes these effects. In women who have a history of NSAID-induced gastrointestinal effects, the use of celecoxib, a cyclooxygenase 2 (COX-2) inhibitor, is an alternative.12,16 Choice of one agent over another may be based on cost, convenience, and patient preference.13 Some research suggests that NSAID therapy should begin at the onset of menses or perhaps even the day before and continued around the clock instead of waiting until symptom onset. The data substantiating this is weak.31 If an NSAID or celecoxib use is contraindicated or not desired, hormonal agents should be considered. Acetaminophen is inferior to NSAID in treatment of this disorder.14,33

Contrary to what often occurs in practice, the data substantiating that dysmenorrhea is best managed when treatment is initiated prior to the start of menses and continued around the clock is weak.33 This is not a “high stakes” controversy given that NSAIDs are relatively inexpensive and the lower risk for gastrointestinal effects given the age of the population of patients affected by this disorder. There is a lack of clinical trial data supporting the optimal dosing regimen for dysmenorrhea, thus improving the patient’s quality of life.

Contemporary dysmenorrhea therapy includes medications and nonpharmacologic treatments. 

**CLINICAL CONTROVERSY**

**PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER**

PMS is a constellation of symptoms including mild mood disturbances and physical symptoms occurring prior to menses and resolving with menses initiation. It is distinct from PMDD.

**EPIEMIOLOGY**

Up to 75% of menstruating women experience PMS symptoms.57 However, a spectrum of premenstrual mood disturbances exists, and PMDD is the most severe. Approximately 3% to 8% of women have PMDD.35,57

**ETIOLOGY AND PATHOPHYSIOLOGY**

PMDD is a complex psychiatric disorder with multiple biological, psychological, and sociocultural determinants.38 Although cyclic hormonal changes are in some way related to PMS and PMDD, the association is neither linear nor simple. When ovulation is suppressed medically or surgically, symptoms improve. Some evidence suggests that PMS and PMDD symptoms are related to low levels of the centrally active progesterone metabolite allospregnanolone in the luteal phase and/or lower cortical γ-aminobutyric acid levels in the follicular phase.54 Women with PMS and PMDD may have enhanced sensitivity to progesterone.55 Studies of the relationship between PMS and PMDD and testosterone levels are conflicting.38 A number of studies suggest a link between PMS and PMDD and low serotonin levels.35,58 Despite similar affective symptoms, hypothalamic–pituitary–adrenal (HPA) axis function in PMS and PMDD is distinct from that seen in major depressive disorder. Specifically, women with PMS show a decrease in stimulated HPA axis response, whereas this response is increased in women with major depressive disorder.54 Although several cross-cultural studies suggest that PMS’ physical symptoms are consistent across cultures, the negative affective symptoms are part of the negative “menstrual socialization” in Western culture.2,58

**PHARMACOECONOMIC CONSIDERATIONS**

For women with third-party coverage for prescriptions, most OCs and the higher NSAID doses used for dysmenorrhea would be covered. For women without such coverage, the OC cost may be prohibitive. Generic forms of NSAIDs in over-the-counter strengths can be considered and are less expensive than marketed topical heat products, such as transdermal topical heat patches. Topical heat can be administered inexpensively via a reusable heating pad or hot water bottle. However, these products are not convenient to use.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Table 89–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of dysmenorrhea.

**Special Populations** Dysmenorrhea is common in adolescent females. The treatment measures used for adult patients are also appropriate for adolescents. Although NSAIDs, topical heat, and OCs are among the top choices, use of the levonorgestrel IUD is also an option.30

**Drug Class Information** Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically relevant drug–drug and drug–food interactions of agents used to treat dysmenorrhea.

**CLINICAL PRESENTATION OF PMDD**

A summary of the American Psychiatric Association’s criteria for PMDD is as follows.1,58

- Symptoms are temporally associated with the last week of the luteal phase and remit with onset of menses.
- At least five of the following symptoms are present: markedly depressed mood, marked anxiety, marked affective lability,
marked anger or irritability, decreased interest in activities, fatigue, difficulty concentrating, changes in appetite, sleep disturbance, feelings of being overwhelmed, and physical symptoms, such as breast tenderness or bloating.

- One of the symptoms must be markedly depressed mood, anxiety, irritability, or affective lability.
- Symptoms interfere significantly with work and/or social relationships.
- Symptoms are not an exacerbation of another underlying psychiatric disorder.
- The criteria are confirmed prospectively by daily ratings over two menstrual cycles.

### Desired Outcome

PMS and PMDD interventions should alleviate the presenting symptoms and subsequently improve quality of life. Table 89–2 lists the various agents used in managing PMS and PMDD and their recommended dosing.

### General Approach to Treatment

A treatment modality that is minimally invasive or without systemic effects is desired for initial therapy. Key to the successful choice of pharmacologic therapy for PMS and PMDD is having the patient chart her specific symptoms for at least 2 months.

### Nonpharmacologic Therapy

Lifestyle interventions should be started and followed for 2 months while the patient charts her symptoms. Although these interventions lack significant supporting clinical trial data, anecdotal reports of efficacy exist. Some lifestyle changes for women with mild-to-moderate premenstrual symptoms include minimizing intake of caffeine, refined sugar, and sodium and increasing exercise.

Vitamin and mineral supplements, such as vitamin B₆ (50–100 mg daily) and calcium carbonate (1,200 mg daily), may help reduce the physical symptoms associated with PMS. A clinical trial review concludes that the following options lack efficacy and safety data and should not be recommended: herbal medicines, homeopathic remedies, dietary supplements, relaxation, massage therapy, reflexology, chiropractic treatments, and biofeedback.

### Pharmacologic Therapy

If symptoms persist after 2 months of symptom charting and lifestyle modifications, pharmacologic therapy for PMDD management is warranted. Over the past decade, the selective serotonin reuptake inhibitors (SSRIs) have been studied significantly for this disorder. Studies have revealed very positive results relative to most symptoms associated with PMDD. Other agents that have been studied and are alternatives include the selective serotonin–norepinephrine reuptake inhibitor venlafaxine, as well as OCs, tricyclic antidepressants, and GnRH agonists.

### Drug Treatments of First Choice

The first-line pharmacologic treatment options for PMDD are the SSRIs. Among this class of agents, data support the use of citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. Whether to dose these agents continuously or only during the luteal phase and the optimal duration of treatment are still not evident.

### CLINICAL CONTROVERSY

Current evidence supports SSRIs as first-line PMDD treatment, either dosed continuously or during the luteal phase alone. Some evidence suggests that SSRI dosing at symptom onset also may be effective. The bulk of studies include women over age 18 years and with treatment durations not longer than 3 to 6 months. Contrary to the excitement surrounding luteal phase dosing, a recent meta-analysis found in favor of the continuous dosing regimen for efficacy. Relapse rates appear to be higher with shorter-duration treatment (4 months vs 12 months). The most effective dosing strategy (continuous, luteal phase, or symptom onset), most efficacious treatments in the adolescent versus perimenopausal populations, and the optimal treatment duration are not evident and warrant further investigation.

The SSRIs are efficacious in more than half of the treated patients compared to less than 30% of those receiving placebo. A meta-analysis reports 50% or greater symptom reduction with SSRI treatment compared to baseline. Improvement often occurs during the first cycle of use.

**Alternative Drug Treatments**

The tricyclic antidepressant clomipramine has been studied for PMDD treatment. In placebo-controlled trials, both continuous daily dosing and luteal phase administration proved effective. Compared with the SSRIs, however, clomipramine is not well tolerated due to its side effects. Venlafaxine has been studied on a continuous daily basis and during the luteal phase. Both venlafaxine regimens resulted in significant symptom improvement (compared to placebo) in more than 60% of treated women.

If treatment with an SSRI or another antidepressant such as clomipramine is unsuccessful, hormonal treatment with a GnRH agonist, such as leuprolide, can be considered. Leuprolide improves premenstrual emotional symptoms as well as some physical symptoms, such as bloating and breast tenderness. However, its cost, the need for intramuscular administration, and its hypoestrogenism side effects (e.g., vaginal dryness, hot flashes, and bone demineralization) limit its use.

The use of a monophasic OC containing 20 mcg of ethinyl estradiol and 3 mg of drospirenone, a progesterone with antiandrogenic effects, improves premenstrual symptoms in women with PMDD. As with the SSRIs, optimal treatment duration is unknown, and superiority to other OCs has not been established.

**Drug Class Information**

Table 89–3 lists the significant pharmacologic properties, common adverse events, and clinically relevant drug–drug and drug–food interactions of the agents used to treat PMDD.

### PHARMACOECONOMIC CONSIDERATIONS

The SSRIs as first-line treatment options for PMDD management are comparably priced overall; however, a generic formulation of fluoxetine is available. Emerging data on the most appropriate dosing regimens may contribute even further to a reduction in the cost of managing this disorder.
EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in PMDD management.

CONCLUSIONS

Treatment success for the various menstruation-related disorders can be measured by the degree to which the care plan (1) relieves or reverses symptoms, (2) prevents or reverses the complications (e.g., osteoporosis, anemia, and infertility as noted with amenorrhea, menorrhagia, and anovulatory bleeding, respectively), and (3) minimizes side effects. The return of a regular menstrual cycle with minimal premenstrual symptoms or symptoms of dysmenorrhea is desirable. Depending on the desire for conception and subsequent therapy, this cycle may be ovulatory or anovulatory.

Once optimal therapy has been identified, the regimen can be continued as long as is deemed necessary. In amenorrhea, discontinuation of therapy may be warranted once menses resumes. In anovulatory bleeding, therapy may be discontinued once ovulatory menstrual cycles return. In menorrhagia, dysmenorrhea, and PMDD, optimal therapy may be continued until symptom resolution or until other health factors affect its continuation. For example, a woman taking OCs for menorrhagia or dysmenorrhea may discontinue them when she desires to become pregnant.

Symptom relief in dysmenorrhea should occur within hours of starting an NSAID or within the next menstrual cycle/menses if using COX-2 inhibitors. Evaluate the patient for improvement of symptoms associated with amenorrhea, menorrhagia, anovulatory bleeding, or PMDD within one to two menstrual cycles. Ask patients at this visit about the type, frequency, and severity of current symptoms compared to their initial presenting symptoms. Refer patients with persistent symptoms for further medical evaluation to identify other underlying issues or complications.

Assess the effectiveness of therapy in resuming normal menstrual cycles with minimal related pain after an appropriate treatment interval (1–2 months). Assess improvement in quality of life measures such as physical, psychological, and social functioning and well-being. Evaluate the patient for adverse drug reactions, drug interactions, and other underlying issues or complications. Table 89–3 lists the common side effects that may occur and the monitoring required. Table 89–4 lists the expected outcome measures for each of the menstruation-related disorders discussed in this chapter.

REFERENCES

ABBREVIATIONS

COX-2: cyclooxygenase 2
FSH: follicle-stimulating hormone
GnRH: gonadotropin-releasing hormone
HPA: hypothalamic–pituitary–adrenal axis
IUD: intrauterine device
LH: luteinizing hormone
MPA: medroxyprogesterone acetate
NSAID: nonsteroidal antiinflammatory drug
OC: oral contraceptive
PCOS: polycystic ovary syndrome
PMDD: premenstrual dysphoric disorder
PMS: premenstrual syndrome
SHBG: sex hormone–binding globulin
SSRI: selective serotonin reuptake inhibitor
Endometriosis should be suspected in any woman of reproductive age, including adolescents, with recurring cyclic or acyclic pelvic pain and/or subfertility.

The etiology of endometriosis is likely multifactorial; no single theory is satisfactory to explain all cases.

No physical examination findings or laboratory tests are considered diagnostic for endometriosis. A definitive diagnosis can be made only via surgical visualization of lesions. Confirmation of diagnosis is not necessary in all cases.

Treatment goals include improvement of painful symptoms and maintenance or improvement of fertility. Therapy is considered successful based on resolution of the patient’s symptoms or achievement of pregnancy.

All medical therapies are equally efficacious in treating endometriosis-related pain based on available evidence. The choice among agents is determined primarily by side effect profile, cost, and individual patient response.

Endometriosis-related pain can be treated by medical or surgical therapy. Empirical medical therapy is likely more cost-effective and is recommended based on consensus guidelines.

Endometriosis-related infertility is unresponsive to medical therapy. Conservative surgical therapy is the preferred treatment.

Endometriosis is a common cause of chronic pelvic pain in women and is associated with infertility. Characterized by the presence of endometrial tissue outside the uterus, endometriosis is a chronic, recurring disease.

Endometriosis should be suspected in women, including adolescents, with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. Therapy is targeted at relieving symptoms and improving fertility.

The prevalence of endometriosis in the general population is estimated to be 5% to 10% of women. Up to 70% of adult women and up to 50% of adolescents presenting with chronic pelvic pain may have endometriosis, and ~20% to 50% of women with infertility may have the disorder. A genetic predisposition for endometriosis has been noted, as evidenced by disease rates that are up to seven times higher in primary relatives of affected women compared with the general population.

An association between endometriosis and ovarian cancer has been reported in the literature. Such reports often suggest that due to this association, aggressive treatment of endometriosis that includes surgical therapy should be recommended for many patients. However, this proposed association between endometriosis and cancer remains controversial. Consequently, data do not exist to enable evidence-based decision making in patients with endometriosis who may be at elevated risk for ovarian cancer.

The etiology of endometriosis is unknown. Multiple mechanisms for development of lesions are likely, including theories of retrograde menstrual flow, coelomic metaplasia, lymphatic and vascular spread, and immunologic abnormalities. Involvement of immune system factors in the development and progression of endometriosis is recognized. Findings of abnormal B- and T-cell function, decreased apoptosis, and altered levels of prostanoids, cytokines, growth factors, interleukins, and aromatase in endometrial lesions and peritoneal fluid of affected women support this theory.

Endometriosis-associated pain is likely secondary to generation of local inflammation by the endometrial lesions, bleeding from the endometrial tissue, and irritation or compression of nerve fibers by endometrial implants. Estrogen has been found to contribute to endometriosis pain due to its role in helping to produce endometrial tissue and in stimulating release of inflammatory substances.
The exact mechanism by which endometriosis reduces fertility is unknown, but it may result from distorted pelvic anatomy, altered peritoneal function, and altered endometrial receptivity that impairs implantation.8

DISEASE STAGING

The severity of disease can be classified according to the American Association of Reproductive Medicine staging system (stage I, mild, to stage IV, severe), but clinical utility of this staging system is limited because findings do not correlate with painful symptoms, nor does the staging system predict pregnancy rates.9,10 Staging may be useful, however, in guiding decisions regarding prognosis and treatment for infertility.9

CLINICAL PRESENTATION

Symptoms

The patient may be asymptomatic or complain of symptoms such as severe dysmenorrhea, deep dyspareunia, chronic pelvic pain (cyclic or acyclic), ovulation pain, cyclical or perimenstrual bowel and bladder complaints (e.g., GI disturbances, painful defecation, dysuria, and/or hematuria), chronic fatigue, or infertility.

Signs

Findings on physical examination are best observed during menstruation and may include pelvic tenderness, tender uterosacral ligaments, enlarged ovaries, or a fixed, retroverted uterus.

Findings on laparoscopic examination may range from a few small lesions located on the ovaries, serosal surfaces, or peritoneum to large cysts called endometriomas. Lesions are often described as "powder burn" or "gunshot" lesions; dark brown, black, or blue lesions, nodules, and cysts; and "chocolate cysts" (endometriomas containing blood).

Diagnosis

Definitive diagnosis can be made only by direct surgical visualization of endometrial lesions; however, treatment guidelines allow for nondefinitive diagnosis in patients presenting with chronic pelvic pain provided that other causes of pain are ruled out and that pain responds to first-line empiric therapies.

TREATMENT

The treatment of endometriosis varies depending on presenting symptoms, patient age, and desired outcome.

DESIRED OUTCOME

Treatment goals for endometriosis depend on the patient’s presentation. Only women with active symptoms (pelvic pain, infertility, or both) require therapy. Depending on the primary complaint, the goals of endometriosis treatment are (a) minimization or removal of endometrial deposits, (b) prevention of disease progression, (c) minimization of associated pain, and (d) prevention or correction of associated infertility.

GENERAL APPROACH TO TREATMENT

The treatment of an asymptomatic patient with endometriosis consists of expectant management (watchful waiting) only because therapy is not indicated unless symptoms develop. For symptomatic patients, the foundation of therapy includes medical treatment, surgical treatment, or both. To date, no studies have directly compared medical and surgical treatment as first-line therapy. Furthermore, determining the optimal medical or surgical approach is difficult secondary to a paucity of well-designed, randomized, controlled trials. All commonly prescribed medical therapies relieve endometriosis-related pain by regressing lesions via induction of a pseudopregnancy or pseudomenopausal state but do not eradicate lesions or improve fertility. Therefore, the choice of initial therapy depends on multiple factors, such as the patient’s primary complaint, the location and extent of disease, the desire for future fertility, the cost of therapy, contraindications to therapy, and potential side effects or complications of therapy.

Guidelines recommend empirical treatment of chronic pelvic pain suspected to be secondary to endometriosis with combined hormonal contraceptives (CHCs) or progestins for at least 3 months.5,9,10 Empiric therapy with a gonadotropin-releasing hormone (GnRH) agonist can also be considered in women, but it is less optimal due to greater expense and toxicity.10 The duration of medical therapy is typically limited to 6 months for drugs with higher toxicity profiles (e.g., danazol and GnRH agonists), but CHCs and progestins may be continued indefinitely.10 Conservative surgical therapy is recommended for treating painful symptoms in women who do not respond to, or have contraindications to, medical therapy or patients with other compelling reasons for surgery. Definitive treatment for endometriosis involves nonconservative surgical therapy via bilateral salpingo-oophorectomy, with or without hysterectomy. This therapy should be reserved for women not desiring future fertility who accept the potential complications of surgically induced menopause. A general treatment algorithm for endometriosis-related pain is shown in Figure 90–1.

For women presenting with infertility as a primary complaint, first-line therapy involves surgical resection of endometrial lesions to restore normal anatomy, followed by watchful waiting.8,9,10 Medical therapy alone is ineffective for endometriosis-related infertility and should be avoided.9,10 For women in whom surgical intervention does not result in pregnancy, controlled ovarian stimulation with intrauterine insemination or in vitro fertilization may be recommended.9–10 Pretreatment with a GnRH agonist for 3 to 6 months prior to in vitro fertilization cycles increases success rates.9 Intrauterine insemination is preferred in women younger than age 35 with milder (stage I or II) disease, whereas in vitro fertilization is preferred in women over age 35 or those with more severe (stage III or IV) disease.8

NONPHARMACOLOGIC THERAPY: SURGERY

Laparoscopy is used in endometriosis as both a diagnostic and a therapeutic tool, and guidelines recommend removal of visible lesions at the time of initial diagnosis.8 Although a significant percentage of women will experience recurrence of painful symptoms after surgery, the use of adjunctive medical therapy postoperatively is no longer recommended due to the lack of documented efficacy at 12 and 24 months.8,10 Conservative
surgical therapy is also the primary treatment of endometriosis-associated infertility.

**PHARMACOLOGIC THERAPY**

Typically, pharmacologic therapy is the first choice for treatment of endometriosis-related pain to minimize risks from surgery. However, drug therapy will not treat endometriosis-related infertility.

**Drug Treatments of First Choice**

First-line therapy for endometriosis-associated pain includes CHCs or progestins. These two drug classes are considered as effective as, and less costly and toxic than, other endometriosis treatments. The choice of agent depends on patient characteristics, such as the desire for contraception, pain patterns, and contraindications. Long-term maintenance therapy with these agents may be considered for women achieving a good therapeutic response. A low-dose combined oral contraceptive administered cyclically was compared with a GnRH agonist in a randomized trial. Both groups showed overall improvement in dyspareunia, nonmenstrual pain, and dysmenorrhea at 6 months. The rate of recurrent symptoms 6 months after cessation of therapy was equal between groups. Combined oral contraceptives can be administered on a continuous basis if desired. Studies on the efficacy of other formulations of CHCs (vaginal ring and transdermal patch) for treatment of endometriosis have not been conducted; however, the use of these agents in endometriosis is reasonable.

Systematic review has concluded that continuous therapy with oral progestins is no more or less effective than other therapies for treatment of endometriosis-associated pain. Two studies of subcutaneous depot medroxyprogesterone revealed statistically equivalent improvement in endometriosis-associated pain compared with the GnRH agonist leuprolide. Studies examining the use of the levonorgestrel-releasing intrauterine device (IUD) also suggest efficacy in the treatment of endometriosis-associated pain, and this device is indicated in evidence-based practice guidelines.

**Alternative Drug Treatments**

Adolescents (younger than 18 years) experiencing chronic pelvic pain despite therapy with first-line therapies should undergo evaluative laparoscopy prior to initiation of additional pharmacotherapy.

In adolescents with endometriosis diagnosed by laparoscopy or in adults with chronic pelvic pain unresponsive to CHCs or progestins, advanced medical therapy for endometriosis pain may be considered.

Agents that can be used as advanced medical therapy include danazol and GnRH agonists. Systematic reviews have concluded that both classes are effective choices, and neither class has been proven superior to the other. The primary difference between treatments is the side effect profile and available dosage forms; therefore, the choice of agent depends on patient age, preference, and tolerance of side effects. Treatment should be continued for 6 months if relief is obtained. For women treated with a GnRH agonist, add-back therapy with an estrogen and progestin combination should be recommended to minimize vasomotor side effects and bone mineral density loss.
The aromatase inhibitors (specifically anastrozole and letrozole) represent one of the newer classes of drugs being investigated for treatment of endometriosis pain. Although early reports of use are positive, the exact role of these agents remains unknown due to the lack of randomized controlled trials, comparative studies, and concern over long-term side effects such as loss of bone mineral density. Despite these uncertainties, one clinical practice guideline does include letrozole as a therapeutic option. However, the type of patient most (or least) suited for such therapy is unknown at this time.

Although once considered first-line treatment for endometriosis-related pain, nonsteroidal antiinflammatory drugs (NSAIDs) have fallen out of favor because of inconclusive evidence of effectiveness. However, NSAIDs may remain an optional, though unproven, treatment for adolescent patients due to concerns over side effects from other non-first-line treatments.

Surgical therapy for endometriosis pain should be performed at the time of diagnosis and again considered for women who do not respond to advanced medical therapy, women with contraindications to medical therapy, and women unable to tolerate side effects caused by medical therapy.

Special Populations: Adolescents

Treatment goals for endometriosis in adolescent patients are pain control, minimization of disease progression, and preservation of fertility. A treatment algorithm that includes therapy for adolescent patients is shown in Figure 90–1. Although progestins are likely to be well tolerated by the adolescent population, clinicians should be aware that efficacy has not been clearly established in this population, and concerns regarding long-term effects on bone mineral density and lipid profile are not clearly defined. The effect of drugs on bone mineral density is of particular concern in young women who have not achieved peak bone mass; thus, add-back therapy should be considered for all adolescents receiving GnRH agonist therapy. Danazol is not likely to be well tolerated by the adolescent population and generally is not recommended for use.

Drug Class Information

When selecting therapy for endometriosis-related pain, the choice of drug within a class often depends on the strength of evidence for efficacy in endometriosis or specific patient factors.

Combined Hormonal Contraceptives CHCs treat the pain of endometriosis by decreasing menstrual flow and regressing endometrial implants through induction of an anovulatory and/or hypoestrogenic state. Continuous therapy also can be used to suppress menstruation and induce a “pseudo-pregnancy”-like state. Evidence-based guidelines consider combined oral contraceptives as effective as other medical therapies for relieving pain from endometriosis. No evidence suggests that one combined oral contraceptive is superior to another. Additionally, although no specific studies have examined the efficacy of the contraceptive patch or vaginal ring in endometriosis, the effects of these agents likely are similar to those of the oral formulations. Thus, the choice between CHCs should be guided by patient preference, likelihood of adherence, and cost. Side effects of CHCs typically are mild and may include nausea, bloating, headache, and breakthrough bleeding. However, all CHCs can increase the risk of thromboembolism, so they should not be used in women with a history of thromboembolism or in smokers over age 35 years.

Administration of CHCs may be cyclic (includes a placebo or nondrug week) or continuous. Although no studies have directly compared the two methods, continuous administration is more likely to induce amenorrhea and therefore may be more beneficial in treating dysmenorrhea.

Progestins Multiple progestins have been studied for the treatment of endometriosis, and all have demonstrated efficacy for treating related pain. Agents available in the United States include oral medroxyprogesterone, depot medroxyprogesterone (both subcutaneous and intramuscular), megestrol, norethindrone, and the levonorgestrel-releasing IUD. The progestins treat endometriosis via atrophy and decidualization of endometrial tissue. They tend to be less expensive and better tolerated than other advanced medical endometriosis treatments.

Common side effects of systemic progestins include breakthrough bleeding, weight gain, fluid retention, and mood swings. For women desiring immediate future fertility after cessation of therapy, progestins may not be optimal secondary to prolonged amenorrhea and anovulation. Also of concern are unknown long-term effects on bone mineral density associated with these agents. Both depot medroxyprogesterone products carry black box warnings against use for more than 2 years. However, in the studies that directly compared the subcutaneous form of depot medroxyprogesterone to leuprolide over a treatment period of 6 months, the extent and degree of bone loss were less severe with the progestin. Specific progestin dosing information is given in Table 90–1.

Gonadotropin-Releasing Hormone Agonists GnRH agonists create a functional oophorectomy via inhibition of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. This, in turn, diminishes endometrial implants. When first initiated, GnRH agonist create an initial gonadotropin flare prior to receptor downregulation that may cause a temporary increase in pain. Initiating therapy during the midluteal phase may minimize such effects.

Therapy with a GnRH agonist is superior to placebo and comparable to danazol for relief of endometriosis-associated pain. Response rates are ~85% to 100% after 6 months of therapy, but recurrence rates at 5 years are 53%. Although a GnRH agonist typically is taken for 6 months, one comparative study has shown equivalent efficacy and recurrence rates between 3 and 6 months of GnRH agonist therapy, and evidence-based guidelines therefore recommend 3 months of therapy as an option. Therapy may also be extended beyond 6 months to maintain efficacy, although data regarding such extended usage are limited.

The three GnRH agonists currently available in the United States are goserelin, leuprolide, and nafarelin. These agents differ primarily by route of administration; therefore, the choice of therapy depends on patient preference. Specific dosing information for the GnRH agonists is given in Table 90–1.

Side effects are the primary limitation of GnRH agonist use. The pharmacologically induced hypoestrogenic environment results in bone loss and vasomotor symptoms such as hot flashes, vaginal dryness, and insomnia. Loss of bone mineral density is estimated at 4% to 6% over 6 months of GnRH agonist therapy and occurs at both the hip and spine, but this loss is partially to fully recoverable upon cessation of the drug. Bone loss is progressive as use of the drugs is extended beyond 6 months; whether reversibility is maintained after such longer treatment periods is unknown. Add-back therapy with estrogen and progesterin combinations has been proven effective for treatment of vasomotor symptoms and...
Pharmacologic Therapy For Endometriosis-Associated Pain

Danazol is a synthetic steroid analogue of 17-ethinyl testosterone. It induces anovulation, amenorrhea, and endometrial atrophy through pituitary suppression of the midcycle LH and FSH surge and induction of a high-androgen, low-estrogen environment. The drug also has immunosuppressive activity that may contribute to its efficacy. Formerly the “gold standard” of endometriosis treatment, the popularity of danazol has decreased with the development of agents with more favorable side effect profiles.

Danazol has proven effective as empirical as well as postoperative therapy. Symptomatic improvement has been reported in up to 80% to 90% of women using the drug, with the best results seen in women achieving amenorrhea. 31 A systematic review concluded that 6 months of danazol therapy is superior to placebo in relieving painful symptoms. 37 The primary limitation of danazol therapy is the high occurrence of androgenic side effects, including weight gain, acne, hot flashes, decreased breast size, hirsutism, and increased low-density lipoprotein cholesterol. Use of vaginal danazol (200 mg/day) has been investigated in one small study, and this route of administration was effective in treatment of endometriosis pain while minimizing systemic side effects. 35 However, more data are needed before this strategy can be routinely recommended.

Danazol should not be initiated in women with hyperlipidemia or liver disease. Danazol is teratogenic, and barrier forms of contraception must be used. The dose of danazol ranges from 200 to 800 mg/day; most studies have used doses of 600 to 800 mg. Specific dosing information is given in Table 90–1.

Nonsteroidal Antiinflammatory Drugs NSAIDs are thought to treat the painful symptoms of endometriosis by interfering with prostaglandin production, but data are lacking to indicate the efficacy of this class of medications specifically in patients with prevention of bone loss while maintaining GnRH agonist efficacy. 36 Add-back therapy dosing should approximate the low doses used for hormone replacement therapy. Thus, CHCs should not be prescribed for this purpose.

Women receiving GnRH agonist therapy should be encouraged to take supplemental calcium and to exercise. One small study suggests that women who exercise (walking and aerobic sessions) during 6 months of GnRH agonist therapy sustain similar bone mineral loss during therapy but have better recovery of bone mineral density after cessation of therapy compared with women who do not exercise. 30

CHCs = combined hormonal contraceptives, GI = gastrointestinal, GnRH-a = gonadotropin-releasing hormone agonists, IM = intramuscular, LNG-IUS = levonorgestrel intrauterine system, MPA = medroxyprogesterone acetate, NSAIDs = nonsteroidal antiinflammatory drugs, sub-Q = subcutaneous.
endometriosis. Long-term use of these agents may be limited by gastrointestinal or renal toxicity. They also may aggravate reactive airway disease and should be used with caution in such patients. Despite this uncertain risk-to-benefit ratio, some clinicians may still wish to try NSAIDs in patients unable to take other endometriosis therapies. NSAIDs commonly used for treatment of gynecologic pain are ibuprofen and naproxen. Specific dosing information is listed in Table 90–1.

Aromatase Inhibitors Aromatase is a key enzyme in the biosynthesis of estrogen, and elevated levels of aromatase have been found in endometrial lesions compared with normal endometrium. Thus, aromatase inhibitors are thought to treat endometriosis pain by direct inhibition of estrogen production. Data on efficacy of aromatase inhibitors in treating endometriosis pain are largely limited to case reports and nonrandomized, noncomparative studies, but there is evidence of efficacy for both letrozole and anastrazole, alone and in combination with GnRH agonists.

Most information about the side effects of aromatase inhibitors comes from data in postmenopausal women. These side effects include hot flashes, vaginal dryness, and loss of bone mineral density. They have been minimized in the endometriosis population by use of add-back therapy. Specific dosing information is listed in Table 90–1.

PHARMACOECONOMIC CONSIDERATIONS

Several cost considerations must be made when choosing endometriosis therapy. The cost of medical therapy must be weighed against the cost of surgical therapy, and the costs of each type of medical therapy must be weighed against another. Unfortunately, no recent data exist that explore the cost-effectiveness of the various treatment options. Generally, GnRH agonists and aromatase inhibitors are the most expensive agents, and CHCs and progestins are the least expensive.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of endometriosis therapy is focused on subjective relief of symptoms. Although objective confirmation of lesion regression by laparotomy is feasible, the results typically are misleading because the number and size of lesions do not correlate well with symptoms.

Endometriosis-related pain should be relieved within 2 months of initiating medical therapy. If symptoms persist, consideration should be given to different medical and/or surgical therapy. For endometriosis-related infertility, most experts recommend 6 months of watchful waiting after surgical intervention. If pregnancy is not achieved within that time, assisted reproductive techniques can be considered.

Careful monitoring of the patient for side effects to recommended drug therapy is important. Most of the monitoring can be accomplished by eliciting any subjective complaints from the patient at routine follow-up visits. However, certain drug therapies may require additional objective monitoring, such as fasting lipid profile and blood pressure measurements. The role of routine bone mineral density testing as a monitoring parameter for patients receiving GnRH agonists or aromatase inhibitors is not yet determined, especially because accuracy of bone mineral density results in predicting fracture risk in younger patients has not been well established, nor has a threshold of loss been established for discontinuation of therapy.

ABBREVIATIONS

CHCs: Combined hormonal contraceptives
FSH: Follicle-stimulating hormone
GnRH: Gonadotropin-releasing hormone
GnRH-a: Gonadotropin-releasing hormone agonist
IUD: Intrauterine device
LH: Luteinizing hormone
LNG-IUS: Levonorgestrel-releasing intrauterine system
NSAIDs: Nonsteroidal antiinflammatory drugs
Nulliparous: having never been pregnant

REFERENCES

The decision to use menopausal hormone therapy must be individualized and based on several parameters, including symptoms, osteoporosis risk, cardiovascular disease risk, breast cancer risk, and thromboembolism risk.

The lowest effective dose of hormone therapy for the shortest duration needed for effective symptom control should be prescribed, weighing the potential benefits and risks for the individual woman.

Hormone therapy is the most effective treatment option for alleviating vasomotor and vaginal symptoms of menopause.

Osteoporosis prevention remains an indicated use of estrogen products; however, nonestrogen products, specifically bisphosphonates, are as effective as hormone therapy for preventing osteoporosis.

Hormone therapy improves depressive symptoms in symptomatic menopausal women, most likely by relieving flushing and improving sleep. However, it may worsen quality of life in women without hot flushes.

Cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular disease, is the leading cause of death among women. Postmenopausal hormone therapy should not be used for reducing the risk of cardiovascular disease.

Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen), hormone therapy in women who have not undergone hysterectomy should include a progestogen in addition to the estrogen.

Use of hormone therapy at doses lower than those prescribed historically is effective in the management of menopausal symptoms.

Results from randomized trials of hormone therapy in postmenopausal women cannot be extrapolated to premenopausal women with ovarian dysfunction. Women with primary ovarian insufficiency need exogenous sex steroids to compensate for decreased production by their ovaries.

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity. By definition, it is a physiologic event that occurs after 12 consecutive months of amenorrhea, so the time of the final menses is determined retrospectively. Women who have undergone hysterectomy must rely on their symptoms to estimate the actual time of menopause.

The median age at the onset of menopause in the United States is 51 years, whereas the average life expectancy for women is 81 years. Thus, American women can expect to be postmenopausal for more than one third of their lives. As the U.S. population ages, the number of women experiencing menopause is expected to rise. Although the age at menarche has declined steadily over centuries, probably as a result of improved nutrition, the age of onset for menopause appears to be relatively stable. Cigarette smokers, however, experience menopause 2 years earlier than nonsmokers on average. Women who have undergone hysterectomy are also more likely to have an earlier menopause despite preservation of their ovaries.

Menopause refers to loss of ovarian function and subsequent hormonal deficiency. This can be due to the normal process of aging (i.e., natural menopause), surgery (total abdominal hysterectomy, bilateral oophorectomy), medications (e.g., chemotherapy), or pelvic irradiation.

Characteristics of the human menstrual cycle throughout reproductive life are well described. A woman is born with approximately two million primordial follicles in her ovaries. During a normal reproductive life span, she ovulates fewer than 500 times. The vast majority of follicles undergo atresia.

The hypothalamic–pituitary–ovarian axis dynamically controls reproductive physiology throughout the reproductive years. The pituitary is regulated by pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH), produced by the pituitary in response to GnRH, regulate ovarian function. These gonadotropins also are influenced by negative feedback from estradiol and progesterone. Ovarian follicular activity is reflected by the circulating concentrations of sex steroids and by peptide hormones (e.g., inhibin and activin). The sex steroids include estradiol,
produced by the dominant follicle; progesterone, produced by the corpus luteum after maturation of the dominant ovarian follicle; and androgens, primarily testosterone and androstenedione, secreted by the ovarian stroma. Sex steroids are important for the healthy functioning of many organs, including the bones, brain, skin, and reproductive and urogenital tracts. They act primarily by regulating gene expression.

Pathophysiologic changes associated with menopause are caused by loss of ovarian follicular activity. Ovarian primordial follicle numbers decrease with advancing age, and at the time of menopause, few follicles remain in the ovary. Hence, the postmenopausal ovary is no longer the primary site of estradiol or progesterone synthesis. The postmenopausal ovary secretes primarily androstenedione and testosterone. In contrast to the acute fall in circulating estrogen at the time of menopause, the decline in circulating androgens commences in the decade leading up to the average age of natural menopause and closely parallels increasing age. Androgens are secreted by both the ovaries and the adrenal glands. Following menopause, direct ovarian androgen secretion appears to account for as much as 50% of testosterone production, with the adrenal gland being a less important source. Hypertrophy of the ovarian stroma may develop after menopause, probably secondary to high LH concentrations, thereby resulting in increased ovarian testosterone production. Alternatively, the ovaries may become fibrotic and a poor source of sex steroids.

No endocrine event clearly signals the time just prior to final menses. Nonetheless, as women age, a progressive rise in circulating FSH and a concomitant decline in ovarian inhibin are observed. In women who continue to experience menstrual bleeding, FSH determinations on day 2 or 3 of the menstrual cycle are considered elevated when concentrations exceed 10 to 12 milli international units/mL (10 to 12 IU/L), an indication of diminished ovarian reserve. Clear elevations in serum FSH are seen in women approximately at age 40 years. When ovarian function has ceased, serum FSH concentrations are greater than 40 milliinternational units/mL (40 IU/L).

**CLINICAL PRESENTATION**

The perimenopause is the period immediately prior to the menopause and the first year after menopause. The menopausal transition is the period of time when the endocrinologic, biologic, and clinical features of the approaching menopause commence. The menopausal transition usually begins approximately 4 years prior to menopause and is characterized by menstrual cycle irregularity caused by increased frequency of anovulatory cycles. Vasomotor symptoms (hot flushes and night sweats), psychological symptoms (anxiety, mood swings, and depression), and disturbances of sexuality are increased markedly in the perimenopause. Menopause is characterized by a 10- to 15-fold increase in circulating FSH concentrations compared with concentrations of FSH in the follicular phase of the cycle, a fourfold to fivefold increase in LH, and a greater than 90% decrease in circulating estradiol concentrations. During the perimenopause, FSH concentrations may rise to the postmenopausal range during some cycles but return to premenopausal levels during subsequent cycles. Thus, high concentrations of FSH should not be used to diagnose menopause in perimenopausal women. However, vasomotor symptoms in perimenopausal women may require treatment despite the presence of menstrual bleeding. Abnormal thyroid function and other conditions that may cause similar symptomatology should be excluded first. Dysfunctional uterine bleeding may occur during the perimenopausal years because of anovulatory cycles, but other gynecologic causes also should be considered. Treatment options for dysfunctional uterine bleeding include progestogens or low-dose oral contraceptives.

**TREATMENT**

Treatment options for menopause include nonpharmacologic therapy for mild symptoms, and hormonal or nonhormonal therapy for moderate to severe symptoms.

**DESIRED OUTCOMES**

Menopause is a natural life event, not a disease. The goals of therapy for menopause are to relieve symptoms and improve quality of life while minimizing adverse effects.

**GENERAL APPROACH TO TREATMENT**

In women with mild vasomotor and/or vaginal symptoms, nonpharmacologic therapy can be considered. However, many women will require pharmacologic therapy for more severe symptoms. Figure 91–1 outlines a treatment algorithm for women requiring pharmacologic therapy. In the absence of contraindications, hormone therapy is appropriate mainly for women with hot flushes and vulvar or vaginal atrophy. It is contraindicated in women with endometrial cancer, breast cancer, undiagnosed vaginal bleeding, coronary heart disease, thromboembolism (including recent spontaneous thrombosis or in the presence of a thrombophilia), stroke or transient ischemic attack, and active liver disease. Relative contraindications include uterine leiomyoma, migraine headaches, and seizure disorder. In addition, oral estrogen should be avoided in women with hypertriglyceridemia, liver disease, and gallbladder disease. For these women, transdermal administration is a safer approach. The main reasons for discontinuing hormone therapy are side effects such as bleeding, breast tenderness, bloating, and “premenstrual-like symptoms.” Reducing the dose or changing the regimen or the route of administration can minimize these effects.
The decision to use hormone therapy must be individualized and based on several parameters, including menopausal symptoms, osteoporosis risk, cardiovascular disease risk, breast cancer risk, and thromboembolism risk.

Clinicians should prescribe the lowest effective dose of hormone therapy for the shortest duration needed for effective symptom control, weighing the potential benefits and risks for the individual woman. Recommendations should be specific to each woman’s clinical profile and concerns. Approved indications of hormone therapy include treatment of vasomotor symptoms and urogenital atrophy and prevention of osteoporosis.

Weighing risks and benefits, the Food and Drug Administration (FDA) determined that the indication for vasomotor symptoms (hot flushes and night sweats) should remain unchanged, but the other two indications for hormone therapy should be revised. For treatment of vasomotor symptoms, systemic hormone therapy remains the most effective pharmacologic intervention (see Fig. 91–1). For symptoms of urogenital atrophy, such as vaginal dryness, intravaginal products should be considered. In addition, although prevention of postmenopausal osteoporosis remains an indicated use of hormone therapy, consideration should be given to approved nonestrogen products, such as raloxifene and bisphosphonates (see Fig. 91–1).

Prior to initiating pharmacologic therapy, a complete medical history and physical examination should be performed. Medical history should include a personal or family history of cardiovascular disease and thrombotic problems. The physical examination should include a complete cardiovascular examination, clinical assessment of thyroid status, and breast and pelvic examinations. Papanicolaou cervical cytologic examination and screening mammography negative for malignancy are required before initiating hormone therapy. Thyroid function tests and lipoprotein lipid profile also are performed at the discretion of the clinician.

Each patient should be evaluated for the presence of indications (i.e., menopausal symptoms such as hot flushes or vaginal dryness) and possible contraindications. A thorough discussion of the risks and benefits of hormone therapy should be completed with the patient so that she can weigh the risks and benefits versus alternatives and make a rational decision about whether to use hormone therapy.

**NONPHARMACOLOGIC THERAPY**

In some women, menopausal symptoms can be managed effectively with lifestyle modifications, including wearing layered clothing that can be removed or added as necessary, lowering room temperature, decreasing intake of hot spicy foods, caffeine, and hot beverages, exercise, and other good general health practices. More recently, dietary supplements and nonpharmacologic therapies have been promoted as “complementary medicine” alternatives to hormone therapy. To date, little evidence supports the use of such nonprescription herbal products, which include various herbal remedies and soy-based supplements.
PHARMACOLOGIC THERAPY

Pharmacologic therapy is the mainstay of management of menopausal symptoms and includes both hormonal (estrogen +/- progestogen) and nonhormonal medications. In the past, hormone therapy has also been used for the prevention of chronic medical conditions (e.g., cardiovascular disease) thought to be associated with loss of female hormones, and estrogen and progestogen therapy for menopause was termed hormone replacement therapy. However, publication of the results of the landmark Women’s Health Initiative study in 2002 shifted the focus toward using estrogen and progestogen at the lowest (instead of replacement) doses needed for the relief of menopausal symptoms only.

Published Guidelines

A number of national and international guidelines and consensus statements on the management of menopause are available. These include position statements from the North American Menopause Society, the Endocrine Society, the American Association of Clinical Endocrinologists, the Society of Obstetricians and Gynaecologists of Canada, the International Menopause Society, and the National Institutes of Health. The United States Preventive Services Task Force also provides a recommendation statement on the use of hormone therapy for the prevention of chronic medical conditions in postmenopausal women. The most current guidelines should be consulted, as menopause is a major area in women’s health with new data being published continuously.

DRUG TREATMENT OF FIRST CHOICE

Hormone therapy is the most effective treatment option for alleviating vasomotor and vaginal symptoms. In women with an intact uterus, hormone therapy consists of an estrogen plus a progestogen. In women who have undergone hysterectomy, estrogen therapy is given unopposed by a progestogen.

Hormone Therapy

Approved indications of postmenopausal hormone therapy include treatment of menopausal symptoms (e.g., hot flushes, night sweats, and urogenital atrophy) and osteoporosis prevention. Much of what is known about the benefits and risks of hormone therapy in postmenopausal women comes from the landmark Women’s Health Initiative (WHI) study. The WHI randomized controlled trial was a chronic disease prevention trial designed to evaluate the role of hormone therapy in reducing the risks of cardiovascular disease in older women and at the same time to investigate the effects on the risk of breast cancer. The trial was conducted in a total of 68,132 mainly asymptomatic women who were an average 12 to 13 years postmenopausal (mean age 63 ± 7.11 years). The continuous combined oral estrogen plus progestogen arm (conjugated equine estrogens 0.625 mg/day plus medroxyprogesterone acetate 2.5 mg/day) of the WHI trial was terminated early. This arm included 16,608 relatively healthy postmenopausal women aged 50 to 79 years at enrollment (mean age 63.2 years). The primary outcome was coronary heart disease (CHD) events, defined as non-fatal myocardial infarction and coronary artery disease death, with invasive breast cancer as the primary adverse outcome. The study also examined secondary outcomes, including stroke, thromboembolic disease, fractures, colon cancer, and endometrial cancer. After a mean follow-up of 5.2 years (planned duration 8.5 years), the Data and Safety Monitoring Board recommended stopping this arm of the trial because of the occurrence of a prespecified level of invasive breast cancer. That is, women who received the active drug had an increased risk of invasive breast cancer (hazard ratio [HR] 1.26, 95% confidence interval [CI] 1–1.59), and the overall risks exceeded benefits. The study also found increased CHD events (HR 1.29, 95% CI 1.02–1.63), stroke (HR 1.41, 95% CI 1.07–1.85), and pulmonary embolism (HR 2.13, 95% CI 1.39–3.25). Beneficial effects included decreases in hip fracture (HR 0.66, 95% CI 0.45–0.98) and colorectal cancer (HR 0.63, 95% CI 0.43–0.92). Results from this study indicated that short-term use (less than 1 year) has risks for CHD and thromboembolic disease events. The number of deaths was similar among the groups.

After a mean follow-up of 7 years, the Data and Safety Monitoring Board also recommended stopping the oral estrogen-alone arm of the study. This arm consisted of 10,739 women who had undergone hysterectomy. Estrogen-only therapy had no effect on coronary heart disease risk and was not associated with increased breast cancer risk but increased stroke risk (HR 1.39, [95% CI 1.1–1.77]) and decreased hip fracture risk (HR 0.61, 95% CI 0.41–0.91).

Among women in the estrogen plus progestogen arm, one serious adverse event occurred in every 100 women treated for 5 years. Specifically, the study suggested that for every 10,000 women taking combined hormone therapy, there would be eight more cases of breast cancer, seven more cases of CHD, eight more cases of stroke, and eight more cases of pulmonary embolism per year. However, six fewer colorectal cancers and five fewer hip fractures would be expected. For the majority of women who had never used hormone therapy before enrolling in the study (6,280 treated with estrogen plus progestogen and 6,024 treated with placebo), the HR for breast cancer was 1.06 (95% CI 0.81–1.38), indicating that the burden of risk for breast cancer resulted from use of hormone therapy for more than 5 years. Subsequently, a large epidemiologic study reported a greater risk estimate of breast cancer for combined estrogen plus progestogen use as well as increased risk for estrogen-only therapy. However, interpretation of these findings is limited by selection bias because the risk profiles of women who used hormone therapy were significantly different from those of nonusers. It is unclear whether the type of estrogen compound or the dose, route, or administration method could be at least partly responsible for the risks observed in the WHI trial.

Regulatory authorities expressed major concerns about hormone therapy use following the publication of the results of the WHI trial and many women either stopped or became reluctant to use hormone therapy. The WHI trial was conducted in older postmenopausal women. No randomized controlled clinical trials of the population of women normally targeted for hormone therapy (i.e., symptomatic perimenopausal or early postmenopausal women) have been reported. Although hormone therapy is not indicated for prevention of chronic diseases of aging, it remains the most effective treatment for vasomotor symptoms, impaired sleep quality, and urogenital symptoms of menopause.

Although it has been proposed that hormone therapy should be prescribed at the lowest possible dose for the shortest possible time, evidence that new low-dose regimens are safer than traditionally prescribed doses is lacking. Weighing the risks and benefits, the FDA mandated the addition of new safety warnings to the labels of all systemic estrogens (regardless of route or dosage form), including estrogen-only and combined estrogen–progestogen products.

The labels caution that use of estrogen–containing hormone therapy regimens by postmenopausal women may be associated with an increased risk of myocardial infarction, stroke, breast cancer, and thromboembolism.

Benefits of Hormone Therapy

Hormone therapy has been shown to relieve vasomotor symptoms, vaginal atrophy, prevent and treat osteoporosis, and reduce the risk of colon cancer.
Vasomotor Symptoms The major indication for postmenopausal hormone therapy is management of vasomotor symptoms. Most women with vasomotor symptoms require hormone treatment for fewer than 5 years, so the risks of therapy appear to be small.

Fewer than 25% of women experience a menopausal transition without symptoms, whereas more than 25% suffer severe menopausal symptoms, most commonly hot flushes and night sweats. Without treatment, hot flushes in most women typically disappear within 1 to 2 years, but in some untreated women hot flushes continue for more than 20 years. Women with mild vasomotor symptoms often experience relief by lifestyle modification and at least 25% of women in clinical trials reported significant improvement of vasomotor symptoms when taking placebo. However, no therapy has been shown to be as effective as estrogen therapy in alleviating significant vasomotor symptoms. Estrogens diminish hot flushes in most women, and all types and routes of administration of estrogen are equally effective. A dose-dependent relationship between estrogen administration and suppression of hot flushes is well established. Some women, especially younger women, may require a higher than average dose of estrogen to suppress symptoms. On the other hand, many women with hot flushes at the time of menopause require lower doses of estrogen. Hormone therapy for menopausal symptoms can be stopped about 2 or 3 years after starting. If treatment can be tapered and stopped within 5 years, no evidence of increased risk of breast cancer is seen.

Vaginal Atrophy Estrogen receptors have been demonstrated in the lower genitourinary tract, and at least 50% of postmenopausal women suffer symptoms of urogenital atrophy caused by estrogen deficiency. Atrophy of the vaginal mucosa results in vaginal dryness and dyspareunia. Lower urinary tract symptoms include urethritis, recurrent urinary tract infection, urinary urgency, and frequency. Most women with significant vaginal dryness because of vaginal atrophy require local or systemic estrogen therapy for symptom relief. Such treatment also reduces the risk of recurrent urinary tract infections, possibly by modifying the vaginal flora. Vaginal dryness and dyspareunia can be treated with an intravaginal estrogen cream, tablet, or ring. In clinical trials, vaginal estrogen appears to be better than systemic estrogen for relieving these symptoms and avoids high levels of circulating estrogen. Concomitant progestogen therapy generally is unnecessary if women are using low-dose micronized 17β-estradiol. However, regular use of conjugated equine estrogens (CEE) vaginal creams and other products that potentially promote endometrial proliferation in women with an intact uterus requires intermittent progestogen challenges (i.e., for 10 days every 12 weeks). This is an important caveat because vaginal atrophy requires long-term estrogen treatment.

Urinary incontinence, which becomes more prevalent with increasing age, usually is not improved by estrogen therapy. In one large clinical trial, estrogen–progestogen therapy actually increased incontinence.

Osteoporosis Prevention and Treatment Therapy directed at menopausal symptoms, such as hot flushes, often is short term. However, therapy directed at prevention of osteoporosis should be long term. For osteoporosis prevention, the advantages of hormone therapy must be weighed against the risks, including thrombosis and the increased incidence of cardiovascular disease and breast cancer; and consideration should be given to approved nonestrogen alternatives.

Postmenopausal osteoporosis is a serious age-related disease that affects millions of women throughout the world. Menopause is accompanied by accelerated bone loss, and the central role of estrogen deficiency in postmenopausal osteoporosis is well established. Osteoporosis is characterized by reduced bone mass associated with architectural deterioration of the skeleton and increased risk for fracture. Estrogen deficiency results in bone loss through its actions in accelerating bone turnover and uncoupling bone formation from resorption. It is important to recognize that bone loss commences 2 years before the final menstrual period. Throughout menopause, the average loss of bone mineral density (BMD) is around 6.4% at the lumbar spine and 4%–5% at the femoral neck, with obese women experiencing less bone loss than nonobese women. Annual bone mass decreases of 0.5% to 1% are seen after age 65 years. An observational study of more than 9,000 postmenopausal women examined the relationship between endogenous estrogens and BMD, bone loss, fractures, and breast cancer. Women with detectable serum estradiol concentrations (5–25 pg/mL [18–92 pmol/L]) had a 6% to 7% higher BMD at the total hip and spine compared with women with undetectable levels (less than 5 pg/mL [18 pmol/L]). They also had significantly less bone loss at the hip than women with undetectable levels. Women with undetectable serum estradiol concentrations had a relative risk of less than 2.5 for subsequent hip and vertebral fractures. However, women with the highest estradiol serum concentrations had the greatest risk of developing breast cancer.

The WHI randomized trial was the first study to demonstrate that hormone therapy reduces the risk of fractures at the hip, spine, and wrist in women not selected for having osteoporosis. Hip and clinical vertebral fractures are reduced by 34%, and total osteoporotic fractures are reduced by 24%. These findings are in agreement with observational data and several meta-analyses of the efficacy of hormone therapy for reducing fractures in postmenopausal women. Estrogen therapy reduces bone turnover and increases bone density in postmenopausal women of all ages. The protective effect persists as long as the treatment is maintained. With cessation of therapy, postmenopausal bone loss resumes at the same rate as in untreated women. The standard bone-sparing daily estrogen dose is equivalent to 0.625 mg CEE. However, lower doses of estrogen have been shown to increase bone mass to the same extent as standard-dose estrogen therapy.

Osteoporosis prevention remains an indicated use of estrogen products; however, nonestrogen products, specifically bisphosphonates, are as effective as hormone therapy for preventing osteoporosis. The FDA has withdrawn the “osteoporosis treatment” indication from estrogen products. Long-term hormone therapy is no longer an appropriate first-choice option for osteoporosis prevention because of the risks associated with its long-term use. Therefore, hormone therapy should be considered for osteoporosis prevention only in women at significant risk for osteoporosis who cannot take nonestrogen treatments such as bisphosphonates.

Bisphosphonates are analogs of pyrophosphate that inhibit bone resorption. Drugs in this class with FDA-approved indications for osteoporosis include alendronate, risedronate, ibandronate, and zoledronic acid. Bisphosphonates reduce the risk of both hip and vertebral fractures by 30% to 50%. Bisphosphonates have no known impact on the incidence of cardiovascular disease or breast or endometrial cancer. A few trials have shown improved bone density over single therapy when a bisphosphonate is combined with estrogen or the selective estrogen receptor modulator raloxifene, but no fracture data are available as of this writing. Some experts recommend cessation of bisphosphonate therapy after 5–10 years use because of accumulation in bone.

General protective measures, such as regular weight-bearing exercise and avoidance of detrimental lifestyle habits such as smoking and alcohol abuse, are appropriate for all women. Some women require calcium supplementation to their dietary intake. Adequate vitamin D intake and/or supplementation is also needed. See Chap. 99 for a full discussion of osteoporosis prevention and treatment.
Colon Cancer Risk Reduction
Colorectal cancer is the fourth most common cancer and the second leading cause of cancer death in the United States (see Chap. 138). The estrogen–progestogen arm of the WHI study was the first randomized controlled trial to confirm that combined estrogen–progestogen therapy reduces colon cancer risk. Compared with placebo, six fewer colorectal cancers are reported per year in every 10,000 women taking hormone therapy.17

Quality of Life, Mood, Cognition, and Dementia
Hormone therapy improves depressive symptoms in symptomatic menopausal women, most probably by relieving flushing and improving sleep.40 Women with vasomotor symptoms receiving hormone therapy have improved mental health and fewer depressive symptoms compared with women receiving placebo; however, hormone therapy may worsen quality of life in women without flushes.41 There is no evidence that hormone therapy improves quality of life or cognition in older, asymptomatic women.50–52

More than 33% of women 65 years and older will develop dementia during their lifetime.43 Several observational studies have suggested that estrogen therapy may be protective against Alzheimer disease (see Chap. 63). The WHI Memory Study (an ancillary study of WHI trial) evaluated the effect of combined hormone therapy on dementia and cognition in 4,532 women 65 to 79 years old.41 The study found that postmenopausal women 65 years and older taking estrogen plus progestogen therapy had twice the rate of dementia, including Alzheimer disease, than women taking placebo (HR 2.05, 95% CI 1.21–3.48).41 In addition, estrogen plus progestogen therapy in these women did not prevent mild cognitive impairment, a cognitive and functional state between normal aging and dementia that frequently progresses to dementia.43 The estrogen alone arm of the WHI trial showed similar findings.46,47

Hormone therapy does not improve quality of life in postmenopausal women who do not have vasomotor symptoms. Hormone therapy does not improve cognitive function compared with placebo and, more importantly, produces an increased risk (albeit small) of clinically meaningful cognitive decline among women 65 years and older taking hormone therapy.41–46,46,47

Other Effects
Diabetes In healthy postmenopausal women, hormone therapy appears to have a beneficial effect on fasting glucose levels in women with elevated fasting insulin concentrations.48 Also, in women with coronary artery disease, hormone therapy reduces the incidence of diabetes by 35%.49 These findings provide important insights into the metabolic effects of hormone therapy but are insufficient to recommend the long-term use of hormone therapy in women with diabetes.

Body Weight A meta-analysis of randomized controlled trials showed that unopposed estrogen or estrogen combined with a progestogen has no effect on body weight, suggesting that hormone therapy does not cause weight gain in excess of that normally observed at the time of menopause.50

Risks of Hormone Therapy
The risks of hormone therapy include ovarian cancer, endometrial cancer, breast cancer, venous thromboembolism, gallbladder disease, and possibly cardiovascular disease in older women. The risks depend on the hormonal regimen used (estrogen only versus estrogen plus progestogen), the route of administration, dose, duration of therapy, age at treatment initiation, and the patient’s other risk factors.

Cardiovascular Disease
Cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular disease, is the leading cause of death among women. The American Heart Association recommends that postmenopausal hormone therapy should not be used for reducing the risk of coronary heart disease.54

In the previous decade, an expectation of coronary benefit had been a major reason for use of postmenopausal hormones because observational studies indicated that women who use hormone therapy have a 35% to 50% lower risk of coronary heart disease than nonusers.52 In addition, previous studies have shown that estrogen exerts protective effects on the cardiovascular system, including lipid-lowering,53 antioxidant,54 and vasodilating effects.54 Nevertheless, recent randomized clinical trials have provided no evidence of cardiovascular disease protection and even some evidence of harm with hormone therapy.17,55–58

The primary findings of the estrogen plus progestogen arm of the WHI trial showed an overall increase in the risk of CHD (HR 1.29, 95% CI 1.02–1.63) among healthy postmenopausal women 50 to 79 years old receiving combined estrogen–progestogen hormone therapy compared with those receiving placebo.57 The primary findings of the estrogen-only arm of the WHI trial show no effect (either increase or decrease) on the risk of coronary heart disease in women taking estrogen alone.18 Subgroup analyses performed in the years after the WHI was first published in 2002 and revealed that women who initiated hormone therapy 10 or more years after the time of menopause tended to have increased CHD risk compared with women who initiated therapy within 10 years of menopause.59,60 Neither estrogen alone or estrogen plus progestogen were associated with a statistically significant effect on CHD in women aged 50–59 years, and hormone therapy was associated with reduced overall mortality, although this decrease was not statistically significant.59

More recently, new analyses from the WHI that included only adherent study participants found that the risk of CHD with estrogen plus progestogen use is increased in the first two years of treatment, even in women aged 50–59 years at study entry. However, the risk of CHD in women who initiated therapy within 10 years of menopause appears to decrease after six years of treatment.61 It is important to remember that all of the above data from the WHI are from secondary analyses. In addition, the mean age of study participants was 63, while the average age of natural menopause is 51. Most women who commence estrogen or estrogen plus progestogen therapy do so within the first few years of becoming menopausal. It is still unclear how the cardiovascular effects of hormone therapy during perimenopause/early menopause and late menopause differ. There is a need for a long-term randomized controlled study of low-dose hormone therapy started around the time of menopause.61 Hormone therapy should not be initiated or continued for the prevention of cardiovascular disease. Adherence to a healthful lifestyle...
(cessation of smoking, regular exercise, healthy diet, and body mass index less than 25 kg/m²) may prevent the onset of cardiovascular disease in postmenopausal women.\textsuperscript{62,63}

In the estrogen plus progestogen arm of the WHI study, the increased risk for stroke and venous thromboembolism continued throughout the 5 years of therapy.\textsuperscript{17} Increased risk was observed only for ischemic stroke and not for hemorrhagic stroke.\textsuperscript{64} In the estrogen-alone arm of the study, a similar increased risk for stroke was observed.\textsuperscript{18}

**Breast Cancer**

The WHI trial found that combined estrogen plus progestogen therapy has an increased risk of invasive breast cancer (HR 1.26, 95% CI 1.0–1.59) and a trend toward increasing risk with increasing duration of therapy.\textsuperscript{17} The estrogen-only arm of the WHI trial found no increased risk for breast cancer during the 7-year follow-up period.\textsuperscript{18} In the estrogen plus progestogen arm, the increased breast cancer risk did not appear until after 3 years of study participation.\textsuperscript{17} The risk was seen only in women who initiated therapy within 5 years of the start of menopause but not in those who started therapy more than 5 years after menopause.\textsuperscript{65} The breast cancers diagnosed in women in the hormone therapy group had similar histology and grade but were more likely to be in an advanced stage compared with women in the placebo group.\textsuperscript{65} The risk of breast cancer returns to baseline rapidly after discontinuation of hormone therapy.\textsuperscript{65} In an unselected postmenopausal population, the Million Women Study found that current use of hormone therapy increased breast cancer risk and breast cancer mortality (relative risk 1.66 and 1.22, respectively). Increased incidence was observed for estrogen-only use (relative risk 1.30), for estrogen plus progestogen (relative risk 2), and for tibolone (relative risk 1.45).\textsuperscript{19}

For women in the United States, the lifetime risk of developing breast cancer is approximately one in eight,\textsuperscript{66} and the greatest incidence occurs in women older than 60 years (see Chap. 136). In a collaborative re-analysis of data from 51 studies evaluating 52,705 women with breast cancer and 108,411 controls, less than 5 years of combined estrogen–progestogen therapy was associated with a 15% increase in breast cancer risk, and the risk increased with longer duration (relative risk 1.35 with 5 or more years of use).\textsuperscript{68} However, 5 years after discontinuation of hormone therapy, the risk of breast cancer was no longer increased.\textsuperscript{69} Addition of progestogens to estrogen may increase breast cancer risk beyond that observed with estrogen alone.\textsuperscript{69} The Iowa Women’s Health Study showed that exposure to hormone therapy is associated with an increased risk of breast cancer that has a favorable prognosis.\textsuperscript{71} These findings have been attributed to increased breast cancer screening in women taking hormone therapy. A study of the effects of hormone therapy in women with a family history of breast cancer found that those who were currently receiving hormone therapy had approximately the same increased relative risk as those who did not have a family history.\textsuperscript{72} The overall mortality for women with a family history of breast cancer from all causes was reduced significantly among hormone therapy users.\textsuperscript{72} These data suggest that hormone therapy use in women with a family history of breast cancer is not associated with a significantly increased incidence of the disease.

Sex steroid deficiency during menopause results in lipomatous involution of the breast, which is seen as decreased mammographic breast density and markedly improved radiotransparency of breast tissue. Thus, mammographic changes indicating breast cancer can be recognized more easily and earlier after the menopause. Conversely, combination hormone therapy results in increased mammographic breast density, and increased density on mammography has been associated with higher breast cancer risk.\textsuperscript{73} Of note, increased mammographic density is not observed with estrogen-only therapy.\textsuperscript{74}

**Endometrial Cancer**

The WHI trial suggests that combined hormone therapy does not increase endometrial cancer risk compared with placebo (HR 0.81, 95% CI 0.48–1.36).\textsuperscript{23} Estrogen alone given to women with an intact uterus significantly increases uterine cancer risk.\textsuperscript{76} The excess risk increases with dose and duration of estrogen (10 years of unopposed estrogen increases the risk 10-fold), is apparent within 2 years of the start of treatment, and persists for many years after estrogen replacement is discontinued.\textsuperscript{24} Estrogen-induced endometrial cancer usually is of a low stage and grade at the time of diagnosis,\textsuperscript{23} and it can be prevented almost entirely by progestogen coadministration. The sequential addition of progestogen to estrogen for at least 10 days of the treatment cycle or continuous combined estrogen–progestogen does not increase the risk of endometrial cancer.\textsuperscript{27}

Lower doses of estrogen may be associated with a lower risk of endometrial hyperplasia.\textsuperscript{78} Raloxifene does not result in endometrial hyperplasia, has no effect on endometrial thickness, is not associated with polyp formation, and has virtually no proliferative effect on the endometrium.\textsuperscript{79} A 4-year trial of raloxifene in women with osteoporosis showed no increased risk of endometrial cancer.\textsuperscript{80}

**Ovarian Cancer**

Lifetime risk of ovarian cancer is low (1.7%). The WHI trial suggests that combined hormone therapy may increase the risk of ovarian cancer (HR 1.58, 95% CI 0.77–3.24).\textsuperscript{75} However, an observational study reported an increased risk of ovarian cancer in women taking postmenopausal estrogen-only therapy for more than 10 years (relative risk 1.8, 95% CI 1.1–3.0 and 3.2, 95% 1.7–5.7 for 10 to 19 years and 20 or more years, respectively) but no increased risk of ovarian cancer among women receiving combination estrogen–progestogen therapy.\textsuperscript{81} A large prospective cohort study in Danish women found that use of hormone therapy was associated with an increased risk of ovarian cancer regardless of duration of use, formulation, dose of estrogen, progestogen type, hormone therapy regimen, and route of administration.\textsuperscript{82}

**Venous Thromboembolism**

Venous thromboembolism, including thrombosis of the deep veins of the legs and embolism to the pulmonary arteries, is uncommon in the general population. The absolute risk of venous thromboembolism in nonhormone therapy users is approximately 1 in 10,000 women.\textsuperscript{83} Women taking combined estrogen–progestogen hormone therapy have a twofold increased risk for thromboembolic events, with the highest risk occurring in the first year of use.\textsuperscript{84} The absolute increase in risk is small, with 1.5 venous thromboembolic events per 10,000 women in 1 year.\textsuperscript{84} Lower doses of estrogen are associated with a decreased risk for thromboembolism as compared with higher doses.\textsuperscript{85} Oral administration of estrogen increases the risk of venous thromboembolism compared to the transdermal route.\textsuperscript{85} Also, the norpregnane progestogens, unlike micronized progesterone and pregnane derivatives (e.g., medroxyprogesterone acetate), appear to be thrombogenic.

Currently, there is no indication for thrombophilia screening before initiating hormone therapy. However, hormone therapy should be avoided in women at high risk for thromboembolic events.

**Gallbladder Disease**

Gallbladder disease is a commonly cited complication of oral estrogen use. The WHI studies reported an increased risk for cholecystitis, cholelithiasis, and cholecystectomy among women taking...
oral estrogen or estrogen–progestogen therapy.\textsuperscript{36} Transdermal estrogen is an alternative to oral therapy for women at high risk for cholelithiasis.

**Estrogens**

Estrogens are naturally occurring hormones or synthetic steroidal or nonsteroidal compounds with estrogenic activity. The primary accepted indication for estrogen-based hormone therapy is the relief of vasomotor symptoms, and the initial dose should be the lowest effective dose for symptom control.

**Adverse Effects** Common adverse effects of estrogen include nausea, headache, breast tenderness, and heavy bleeding. More serious adverse effects include increased risk for CHD, stroke, venous thromboembolism, breast cancer, and gallbladder disease.

Initiating therapy with low doses of estrogen often will minimize breast tenderness, unscheduled bleeding, and potentially other adverse effects. Transdermal estradiol is less likely than oral estrogen to cause nausea and headache. Also, transdermal estradiol is associated with a lower incidence of breast tenderness and deep vein thrombosis than is oral estrogen.\textsuperscript{25,37,38} In many cases changing from one estrogen regimen to another can alleviate certain adverse effects. Lower dose estrogen therapy is also associated with less mastalgia.

**Dose and Administration** Various systemically administered estrogens (typically oral and transdermal) are suitable for replacement therapy (Tables 91–1 and 91–2). Estrogens can be administered orally, percutaneously (transdermal patches and topical products), intravaginally (creams, tablets, or rings), intramuscularly, and even subcutaneously in the form of implanted pellets. The choice of estrogen delivery (product, route, and method) should be determined in consultation with the patient to ensure acceptability and enhance adherence. In general, the oral and transdermal routes are used most frequently, with oral conjugated equine estrogens (CEE) particularly popular in the United States. No evidence indicates that one estrogen compound is more effective than another in relieving menopausal symptoms or preventing osteoporosis.

**Oral Estrogen** Oral CEE has been available for more than 50 years. CEE is prepared from the urine of pregnant mares and is composed of estrone sulfate (50% to 60%) and multiple other equine estrogens such as equilin and 17α-dihydroequilin.\textsuperscript{39}

Estradiol is the predominant and most active form of endogenous estrogens. A micronized form of estradiol (produced by a technique that yields extremely small particles of the pure hormone) is readily absorbed from the small intestines.\textsuperscript{40} When given orally, estradiol is metabolized by the intestinal mucosa and the liver during the first hepatic passage, and only 10% reaches circulation as free estradiol. Metabolism of estrogen is partly mediated by the cytochrome P450 3A4 isoenzyme. Gut and liver metabolism converts a large proportion of estradiol to the less potent estrone. Thus, measurement of serum estradiol is not useful for monitoring oral estrogen replacement. The principal metabolites of micronized estradiol are estrone and estrone sulfate. Administration of estradiol via the oral route results in estrone concentrations that are three to six times those of estradiol. Ethinyl estradiol is a highly potent semisynthetic estrogen that has similar activity following administration by the oral or parenteral route.

Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone–binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens.

**Other Routes** Non-oral forms of estrogens (including transdermal, topical, and intravaginal) bypass the gastrointestinal tract and thereby avoid first-pass liver metabolism. These routes of estradiol delivery result in a more physiologic estradiol-to-estrone ratio (estradiol concentrations greater than estrone concentrations), as seen in the normal premenopausal state. Transdermal estrogen therapy also is less likely to affect sex hormone–binding globulin

\textsuperscript{a} Systemic oral and transdermal estrogen and progestogen combination products are available in the United States.

\textsuperscript{b} Systemic oral estrogen and androgen combination products are available in the United States.

\textsuperscript{c} U.S. brand names.

\textsuperscript{d} Not available in the United States.

\textsuperscript{e} Women with elevated triglyceride concentrations or significant liver function abnormalities are candidates for non-oral estrogen therapy.
compared with oral therapy. These regimens produce little or no change in circulating lipids, coagulation parameters, or C-reactive protein levels.90

Transdermal estrogens share the advantages of other non-oral estrogen routes and have the added advantage of delivering estradiol to the general venous circulation at a continuous rate. Reactions at the application site occur in approximately 10% of women who use reservoir (alcohol-based) patches. The newer matrix systems (estrogen in adhesive) generally are better tolerated, and fewer than 5% of women experience skin reactions.91 The incidence of skin irritation diminishes when the application site is rotated. Topical antiinflammatory products (e.g., hydrocortisone cream) can be applied for managing the rashes, and switching to another transdermal patch is often a viable option.

Topical preparations (gels, sprays, and emulsions) are convenient, but variability in drug absorption is common. This form of estrogen is also used for systemic therapy. Estradiol pellets (implants) containing pure crystalline 17β-estradiol have been available for more than 50 years. They are inserted subcutaneously into the anterior abdominal wall or buttock. Pellets are difficult to remove and may continue to release estradiol for a long time after insertion. Implantation should not be repeated until serum estradiol concentrations have fallen to values similar to those at the midfollicular phase of the menstrual cycle. Estradiol pellets are not available in the United States.

Intravaginal creams, tablets, and rings are used for treatment of urogenital (vulval and vaginal) atrophy. However, this route of administration can have more than just a local effect. Systemic estrogen absorption is lower with vaginal tablets and rings (specifically Estring) compared with vaginal creams. Nonetheless, local application of the cream at low doses can reverse atrophic vaginal changes and avoid significant systemic exposure. Nonestrogen vaginal moisturizers and lubricants also may provide local symptom relief. These products can be used alone or in combination with locally-acting intravaginal estrogens. Intravaginal rings are a sustained-release delivery system composed of a biologically inert liquid polymer matrix with pure crystalline estradiol that can maintain adequate estradiol concentrations. One such intravaginal ring product (Femring) is designed to achieve systemic concentrations of estrogen and is indicated for treatment of moderate to severe vasomotor symptoms.

Progestogens

Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen), women who have not undergone hysterectomy should be treated concurrently with a progestogen in addition to the estrogen.92

Progestogens reduce nuclear estradiol receptor concentrations, suppress DNA synthesis, and decrease estrogen bioavailability by increasing the activity of endometrial 17-hydroxysteroid dehydrogenase, an enzyme responsible for converting estradiol to estrone.76

The first generation of progestogens included the C-19 androgenic progestogens norethindrone (also known as norethisterone), norgestrel, and levonorgestrel. More recent preparations have included the C-21 progestogens dydrogesterone and medroxyprogesterone acetate, which are less androgenic. Drosipirenone, a synthetic progestogen analog of the potassium-sparing diuretic spironolactone, has both antiandrogenic and antialdosterone properties. Micronized progesterone also has become available for use in postmenopausal women. The most commonly used oral progestogens are medroxyprogesterone acetate, micronized progesterone, and norethindrone acetate. The latter now can be administered transdermally in the form of a combined estrogen–progestogen patch.

**Adverse Effects**

Common adverse effects of progestogens include irritability, depression, and headache. Changing from a cyclic to a continuous-combined regimen or changing from one progestogen to another may decrease the incidence or severity of untoward effects. Adverse effects of progestogens are difficult to evaluate and can vary with the agent administered. Some women experience “premenstrual-like” symptoms, such as mood swings, bloating, fluid retention, and sleep disturbance. New methods and routes of progestogen delivery (e.g., by an intranasal spray or locally by an intruterine device that releases levonorgestrel or a progestone-containing bioadhesive vaginal gel) may be associated with fewer adverse effects. Women who are unable to tolerate a progestogen may be given unopposed estrogen if they are informed of the significant increased risk for endometrial cancer and have endometrial biopsy annually or whenever breakthrough vaginal bleeding occurs.

**Dose and Administration**

Several progestogen regimens designed to prevent endometrial hyperplasia are available (Table 91–3). Progestogens must be taken for a sufficient period of time during each cycle. A minimum of 12 to 14 days of progestogen therapy each month is required for complete protection against estrogen-induced endometrial hyperplasia.90 Of note, use of even low-dose estrogen, including some intravaginal preparations, requires progestogen coadministration for endometrial protection in women with an intact uterus.94 However, rarely is progestogen administration needed in women who have undergone hysterectomy.

### Methods of Combined Estrogen and Progestogen Administration

Four combination estrogen and progestogen regimens currently in use are continuous cyclic (sequential), continuous combined,
Continuous long-cycle (or cyclic withdrawal), and intermittent combined (or continuous-pulsed) hormone therapy. The latter two were introduced during the past decade. Sequential hormone therapy results in scheduled vaginal withdrawal bleeding but often is scant or completely absent in older women. For many women, scheduled withdrawal bleeding is one of the main reasons for avoiding or discontinuing hormone therapy. Because there is no physiologic need for bleeding, new hormone therapy regimens that reduce monthly bleeding (e.g., continuous long-cycle regimens) or prevent monthly bleeding (e.g., continuous combined and intermittent combined regimens) have been developed. Various hormone therapy regimens that combine an estrogen and a progestogen are available (Table 91–4).

### Continuous Cyclic Estrogen–Progestogen (Sequential) Treatment
Estrogen typically is administered continuously (daily). A progestogen is coadministered with the estrogen for at least 12 to 14 days of a 28-day cycle. The progestogen causes scheduled withdrawal bleeding in approximately 90% of women. With this regimen, bleeding usually begins 1 to 2 days after the last progestogen dose. Occasionally, bleeding begins during the latter phase of progestogen administration.

#### Continuous Combined Estrogen–Progestogen Treatment
Continuous combined estrogen–progestogen administration results in endometrial atrophy and the absence of vaginal bleeding. However, initially it causes unpredictable spotting or bleeding, which usually resolves within 6 to 12 months. Decreasing the estrogen dose or increasing the progestogen dose usually decreases or stops the spotting. Occasionally, a drug-free period of 1 or 2 weeks is useful to stop the bleeding.

Women who recently have undergone menopause have a higher risk for excessive, unpredictable bleeding while receiving continuous therapy; thus, this regimen is best reserved for women who are at least 2 years postmenopause. Continuous combined hormone therapy is more acceptable than traditional cyclic therapy.

#### Continuous Long-Cycle Estrogen–Progestogen Treatment
In order to decrease the incidence of uterine bleeding, a modified sequential regimen has been developed. In the continuous long-cycle (or cyclic withdrawal) estrogen–progestogen regimen, estrogen is given daily, and progestogen is given six times per year, every other month for 12 to 14 days, resulting in six periods per year. Bleeding episodes may be heavier and last for more days than withdrawal bleeding with continuous cyclic regimens. The effect of continuous long-cycle estrogen–progestogen treatment on endometrial protection is unclear.

#### Intermittent Combined Estrogen–Progestogen Treatment
The intermittent combined estrogen–progestogen regimen, also called continuous-pulsed estrogen–progestogen or pulsed-progestogen, consists of 3 days of estrogen therapy alone, followed by 3 days of combined estrogen and progestogen, which is then repeated without interruption. This regimen is designed to lower the incidence of uterine bleeding. It is based on the assumption that pulsed-progestogen administration will prevent down-regulation of progesterone receptors that can be produced by continuous combined regimens. The lower progestogen dose induces fewer side effects and can be better tolerated. The long-term effect of intermittent combined regimens in endometrial protection is undetermined.

### Low-Dose Hormone Therapy
Increasingly, it has become recognized that use of hormone therapy at doses lower than those prescribed historically is effective in the management of menopausal symptoms (see Table 91–2). The standard dose of estrogen previously believed to be effective in alleviating vasomotor symptoms is equivalent to 0.625 mg CEE, but new evidence indicates that lower doses of estrogen also are effective in controlling postmenopausal symptoms and reducing bone loss. The Women’s Health, Osteoporosis, Progestin, Estrogen (HOPE) trial demonstrated equivalent symptom relief and bone density preservation without an increase in endometrial hyperplasia using lower doses of hormone therapy (CEE 0.45 mg/day and medroxyprogesterone acetate 1.5 mg/day). Even ultralow doses of 17β-estradiol delivered by a vaginal ring (Estring) improved serum lipid profiles and prevented bone loss in elderly women. Whether lower doses of estrogen will be safer (lower incidence of venous thromboembolism and breast cancer) remains to be proven. Nonetheless, evidence of harm associated with a standard dose of hormone therapy has prompted many patients to either discontinue such therapy or taper to lower doses. In general, if adverse effects such as breast tenderness occur with initial doses, lowering the dose may resolve the problem and improve patient adherence. Alternatively, if vasomotor symptoms are not controlled adequately with a lower-dose regimen, increasing the estrogen dose may be a reasonable option.

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate; NETA, norethindrone acetate.
Other oral (drospirenone and norgestimate) and transdermal (levonorgestrel) progestogens also are available in combination with an estrogen.

*Estrogen alone for days 1–14, followed by estrogen–progestogen on days 15–28.
Although some clinicians believe that estrogen can be used safely at lower doses to treat postmenopausal women with severe and protracted vasomotor symptoms, others caution that such long-term therapy, even with lower doses of estrogen, may be associated with unacceptable risks.

**Bioidentical Hormones**

Bioidentical hormone therapy has received much attention by patients, health care professionals, and the media since the initial publication of the WHI results. Bioidentical hormone therapy refers to the practice of using natural (e.g., estrone, estradiol, estradiol progesterone, and testosterone), rather than synthetic, formulations of sex hormones. Often, these hormones are compounded to make a variety of topical formulations, in theory to individualize hormone therapy based on each patient’s specific physiologic hormone levels as measured via salivary concentrations. This strategy is thought to reduce the risk of adverse effects. However, there is a paucity of evidence regarding both their efficacy and safety. 101 Bioidentical hormones appear to carry the same risks as traditional hormone therapy. Several major medical organizations, along with the FDA, have released statements that dissuade against the use of this treatment strategy. 102,103

### ALTERNATIVE DRUG TREATMENTS

In women who have contraindications to estrogen and progestogen use, prefer not to take estrogen and/or progestogen, or cannot tolerate estrogen and/or progestogen administration, a number of other medications may be considered, depending on the goals of therapy. These include the prescription medications testosterone, raloxifene, and tibolone (not currently available in the United States) as well as nonhormonal prescription medications (e.g., selective serotonin reuptake inhibitors). Some women prefer to use herbal medicines and other natural therapies but the efficacy and safety of these methods have not been definitively established.

Alternatives to estrogen for treatment of hot flushes include tibolone, selective serotonin reuptake inhibitors (e.g., paroxetine, fluoxetine), dual serotonin and noradrenaline reuptake inhibitors (e.g., venlafaxine), medroxyprogesterone acetate, megestrol acetate, clonidine, and gabapentin (Table 91–5). 104 Progestogens alone may be an option for some women (e.g., those with a history of breast cancer or venous thrombosis), but weight gain, vaginal bleeding, and other adverse effects often limit their use. Tibolone and progestogens cannot be considered nonhormonal agents for treatment of hot flushes in women for whom hormone therapy is contraindicated. For this group of patients, selective serotonin reuptake inhibitors and venlafaxine are considered by some to be a first-line therapy. 104,105 However, the efficacy of venlafaxine for treatment of hot flushes has not been shown to extend beyond 12 weeks. 106 Furthermore, in breast cancer patients, evidence suggests that selective serotonin reuptake inhibitors could interfere with metabolism of endocrine therapies, such as tamoxifen via cytochrome P450 2D6 inhibition. 107 Clonidine is often effective for symptom control, but its side effects (e.g., sedation, dry mouth, hypotension) are not always well tolerated by women.

### Androgens

Pathophysiologic states affecting ovarian and adrenal function, along with aging, have been associated with androgen deficiency in women. 108 The therapeutic use of testosterone in women, although controversial, is becoming more widespread despite the lack of accurate clinical or biochemical findings of androgen deficiency. 109 Androgens have important biologic effects in women, acting both directly via androgen receptors in tissues, such as bone, skin fibroblasts, hair follicles, and sebaceous glands, and indirectly via the aromatization of testosterone to estrogen in the ovaries, bone, brain, adipose tissue, and other tissues.

**Efficacy**

A cluster of symptoms that characterizes androgen insufficiency in women, manifested as diminished sense of well-being, persistent or unexplained fatigue, and sexual function changes such as decreased libido, decreased sexual receptivity, and decreased pleasure, has been reported. 108 However, studies designed to evaluate this have shown no relationships between serum total and free testosterone levels and either sexual function 109 or well-being 110 in women. Thus, as data supporting an androgen deficiency syndrome are lacking, in 2006 the American Endocrine Society recommended against making a diagnosis of androgen deficiency in women at the present time. 109 Several large randomized placebo-controlled clinical trials involving naturally 111,112 and surgically 113 postmenopausal women presenting with low libido demonstrate that testosterone therapy, with and without concurrent estrogen therapy, improves the quality of the sexual experience, with preliminary data that this may also apply to premenopausal women. 114

**Adverse Effects**

Absolute contraindications to androgen therapy include pregnancy or lactation and known or suspected androgen-dependent neoplasia. Relative contraindications include concurrent use of CEEs (for parenteral testosterone therapy), low sex hormone–binding globulin level (below the normal range for women) moderate to severe acne, clinical hirsutism, and androgenic alopecia.

Adverse effects from excessive dosage include virilization, fluid retention, and potentially adverse lipoprotein lipid effects, which are more likely with oral administration. There is no evidence that systemic transdermal testosterone is associated with increased

*Not available in the United States.
cardiovascular morbidity or mortality\textsuperscript{113} or of a significant change in the risk of invasive breast cancer.\textsuperscript{116,117} However, further studies are required to determine the long term safety of testosterone in women.

**Dose and Administration** Testosterone is available as oral methyltestosterone in the United States and as testosterone implants in the United Kingdom. Of the available oral preparations, methyltestosterone in combination with esterified estrogen (either 0.625 mg esterified estrogen plus 1.25 mg methyltestosterone or 1.25 mg esterified estrogen plus 2.5 mg methyltestosterone) is the most widely studied.

Testosterone replacement for women is available in a variety of formulations (Table 91–6). Most of the studies showing clinical improvement with testosterone therapy reported supraphysiologic levels. More recent studies using transdermal patch therapy have shown efficacy with free testosterone levels in the upper normal range for young women. The availability of testosterone regimens specifically designed for women has the potential to maintain testosterone levels within the normal range and help to clarify whether the apparent beneficial effects of testosterone therapy are physiologic or pharmacologic.\textsuperscript{113,118} In general, testosterone treatment can be administered to postmenopausal women with and without concurrent estrogen therapy. At present, generalized use of testosterone is not recommended because the indications are inadequate, and evidence from long-term studies evaluating safety is lacking.\textsuperscript{119}

### Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) are a group of nonsteroidal compounds that are chemically distinct from estradiol. They act as estrogen agonists in some tissues, such as bone, and as estrogen antagonists in other tissues, such as breast, through specific, high-affinity binding to the estrogen receptor.

**Efficacy** The ideal SERM would protect against osteoporosis and decrease the incidence of breast, endometrial, and colorectal cancer and coronary heart disease without exacerbating menopausal symptoms or increasing the risk of venous thromboembolism or gallbladder disease. To date, no SERM meets these ideals. Tamoxifen, the first-generation SERM (a nonsteroidal triphenylethylene derivative), has estrogen antagonist activity on the breast and estrogen-like agonist activity on bone and endometrium. The second generation of SERMs, most notably raloxifene (a nonsteroidal benzothiophene derivative), has become available for prevention of osteoporosis. Raloxifene does not alleviate, and may even exacerbate, vasomotor symptoms.

The Multiple Outcomes of Raloxifene Evaluation (MORE), a multicenter randomized, blinded, placebo-controlled trial, showed that raloxifene increases BMD in the spine and femoral neck and reduces the risk of vertebral fractures.\textsuperscript{120} It has not been shown to decrease the risk of hip fractures. Raloxifene decreases bone loss in recently menopausal women without affecting the endometrium and has estrogen-like actions on lipid metabolism.\textsuperscript{120} More importantly, the same study\textsuperscript{121} and the Continuing Outcomes Relevant to Evista (CORE) trial\textsuperscript{122} suggest that raloxifene use is associated with a significantly lower incidence of breast cancer compared with placebo. This benefit is primarily due to a reduced risk of estrogen receptor–positive invasive breast cancers.\textsuperscript{80,122} A prospective randomized double-blinded trial of 19,747 women at high risk for breast cancer (Study of Tamoxifen and Raloxifene [STAR]) showed that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer and has a lower risk of thromboembolic events.\textsuperscript{123} A prospective randomized study (Raloxifene Use for the Heart [RUTH]) of 10,101 postmenopausal women (mean age 67.5 years) with coronary heart disease or multiple risk factors for coronary heart disease showed that raloxifene did not significantly affect the risk of coronary heart disease.\textsuperscript{80} Raloxifene does not have a significant effect on cognitive function; however, there is a trend toward a smaller decline in verbal memory and attention scores among women receiving raloxifene.\textsuperscript{124}

**Adverse Effects** Raloxifene is commonly associated with hot flushes and less often with leg cramps. Raloxifene use increases the risk of venous thromboembolism\textsuperscript{80,120–122} and fatal stroke\textsuperscript{80} to a degree similar to that of oral estrogen.

**Dose and Administration** Raloxifene is FDA-approved for the treatment and prevention of osteoporosis and for the reduction of the risk of invasive breast cancer in postmenopausal women with osteoporosis as well as postmenopausal women at high risk for invasive breast cancer. The dose is 60 mg orally once daily.

### Tibolone

Tibolone is a gonadomimetic synthetic steroid in the norpregnane family with combined estrogenic, progestogenic, and androgenic activity.\textsuperscript{125} Tibolone has been used for 2 decades in Europe for treatment of menopausal symptoms and prevention of osteoporosis but is currently not available in the United States. The hormonal effects of this synthetic steroid depend on its metabolism and activation in peripheral tissues. The parent compound has been described as a prodrug that is metabolized quickly in the gastrointestinal tract. It has several active metabolites, including a Δ4-isomer and 3α-OH and 3β-OH compounds.\textsuperscript{125} The Δ4-isomer metabolite confers significant progestogenic and androgenic properties.

**Efficacy** Tibolone has beneficial effects on mood and libido and improves menopausal symptoms and vaginal atrophy. Tibolone protects against bone loss and significantly reduces the risk of vertebral fractures in postmenopausal women with osteoporosis.\textsuperscript{126} It has also been shown to decrease the risk of breast cancer and colon cancer in older women (aged 60–85 years) in one randomized study.\textsuperscript{127} It is also more effective than conventional hormone therapy for management of sexual dysfunction.\textsuperscript{128}

**Adverse Effects** Tibolone use in elderly women has been reported to be associated with an increased risk of stroke.\textsuperscript{126,127} Tibolone lowers concentrations of total cholesterol, triglycerides, and lipoprotein (a) but may decrease high-density lipoprotein (HDL) cholesterol.\textsuperscript{49} The Million Women Study, an observational cohort study, found a greater risk of endometrial cancer (adjusted relative risk 1.79, 95% CI 1.43–2.25).\textsuperscript{129} However, other randomized placebo-controlled studies...
have not shown an increased risk of endometrial cancer with tibolone and suggest that tibolone has an endometrial safety profile similar to continuous combined CEE and medroxyprogesterone acetate.\textsuperscript{130}

The most commonly reported adverse effects of tibolone include weight gain and bloating.

**Complementary and Alternative Medicine**

Some women prefer to use natural remedies due to a belief that they are safer. Randomized, placebo-controlled trials of complementary and alternative therapies have been equivocal and have not established the safety and efficacy of herbal remedies, homeopathic treatments, or acupuncture for the prevention or treatment of hot flushes.

**Phytoestrogens** Phytoestrogens have physiologic effects in humans.\textsuperscript{131} They are plant compounds with estrogen-like biologic activity and relatively weak estrogen receptor–binding properties. Epidemiologic studies suggest that consumption of a phytoestrogen-rich diet, which is common in traditional Asian societies, is associated with a lower risk of breast cancer.\textsuperscript{131}

The biologic potencies of phytoestrogens vary. Most of these compounds are nonsteroidal and are less potent than synthetic estrogens. The three main classes of phytoestrogens are isoflavones, lignans, and coumestans, all of which are found in plants or their seeds.\textsuperscript{131} The most commonly studied phytoestrogen is the isoflavone class. Genistein and daidzein are the most abundant active components of isoflavones. The concentration of isoflavones per gram of soy protein varies considerably among preparations. Also, a single plant often contains more than one class of phytoestrogen. Common food sources of phytoestrogens include soybeans (isoflavones), cereals, oils such as flaxseed (lignans), and alfalfa sprouts (coumestans).

Mild estrogenic effects have been seen in postmenopausal women,\textsuperscript{131} but current data suggest that phytoestrogen supplementation is no more effective than placebo in relieving hot flushes or other symptoms of menopause in postmenopausal women.\textsuperscript{132}

Phytoestrogens decrease low-density lipoprotein (LDL) cholesterol and triglyceride concentrations with no significant change in HDL cholesterol concentrations.\textsuperscript{133} Furthermore, phytoestrogens have the ability to inhibit LDL oxidation and normalize vascular reactivity in estrogen-deprived primates.\textsuperscript{134} In addition, BMD may be improved by phytoestrogens.\textsuperscript{131} Common adverse effects include constipation, bloating, and nausea.\textsuperscript{134}

A recent meta-analysis reported that phytoestrogen use is not associated with increased rates of endometrial cancer, vaginal bleeding, and breast cancer.\textsuperscript{134} Large, long-term studies are needed to further document the effects of phytoestrogens on the breast, bone, and endometrium. Furthermore, differences among classes of phytoestrogens must be identified clearly, including dosing and biologic activity, before phytoestrogens can be considered an alternative to conventional hormone therapy in postmenopausal women.

**Other Herbal Products** Black cohosh (Cimicifuga racemosa or Actaea racemosa), a widely used herbal supplement, may not offer substantial benefits for relief of vasomotor symptoms as suggested by earlier trials.\textsuperscript{135} This substance does not appear to have strong intrinsic estrogenic properties but may act through the serotonergic system. Black cohosh appears to be generally well tolerated, although hepatotoxicity has been reported. It is unclear if this is due to the herb itself or adulterations of commercially available products.\textsuperscript{136} The long-term effects of black cohosh are unknown.

Other herbs and alternative treatments that may be used by women include dong quai, red clover leaf (contains phytoestrogens), kava, and dehydroepiandrosterone. These have not been shown to be effective in the treatment of menopausal symptoms and may carry the risk of adverse events.\textsuperscript{137}

**EVALUATION OF THERAPEUTIC OUTCOMES**

After the menopausal woman begins hormone therapy, a brief follow-up visit 6 weeks later may be useful to discuss patient concerns about hormone therapy and to evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding. The FDA recommends that women who choose estrogen-based therapy should have yearly breast examinations, perform monthly breast self-examinations, and receive periodic mammograms (scheduled based on their age and risk factors). Also, women receiving hormone therapy should undergo annual monitoring, including a medical history, physical examination, pelvic examination, blood pressure measurement, and routine endometrial cancer surveillance, as indicated. Additional follow-up is determined based on the patient’s initial response to therapy and the need for any modification of the regimen. An ultrasound, ideally transvaginal, and where indicated an endometrial biopsy should be performed in women taking cyclic hormone therapy if vaginal bleeding occurs at any time other than the expected time of withdrawal bleeding or when heavier or more prolonged withdrawal bleeding occurs. In women taking continuous combined hormone therapy, endometrial evaluation should be considered when irregular bleeding persists for more than 6 months after initiating therapy. However, there is no universal agreement that endovaginal ultrasonography is adequate for excluding endometrial pathology.

The main indication for hormone therapy is relief of menopausal symptoms, and hormone therapy should be used only as long as symptom control is necessary (typically 2–3 years). When hormone therapy is used under such conditions, the absolute risk of harm to an individual woman is very small.\textsuperscript{17}

Many women have no difficulty abruptly stopping hormone therapy; others develop vasomotor symptoms after discontinuation. Although these symptoms usually are mild and resolve over a few months, in some women the symptoms are severe and intolerable. Few studies have addressed the appropriate method for discontinuing hormone therapy. There is no evidence that gradual discontinuation of hormone therapy reduces the recurrence of hot flushes compared with sudden discontinuation. Studies determining effective ways to reduce symptoms of estrogen withdrawal are needed.

**Pharmacoeconomic Considerations**

Estrogens and progestogens used for postmenopausal hormone therapy are prescribed commonly in the United States, especially for the management of menopausal vasomotor symptoms. Even before publication of the WHI trial findings, only a fraction of women filled their hormone therapy prescriptions, and only 25% to 40% continued to take postmenopausal hormone therapy for more than 1 year.\textsuperscript{138} This may be due to women’s attitudes toward hormone therapy or a result of fear about adverse effects and associated risks. Hormone therapy use in the United States declined substantially after dissemination of the WHI trial results.\textsuperscript{139}

Use of hormone therapy for the management of vasomotor symptoms is cost effective, and data supporting the use of nonhormonal alternatives are limited. The cost of hormone therapy varies depending on the route and method of delivery. Transdermal preparations are about twice as expensive as their equivalent oral preparations.\textsuperscript{140} Women who have undergone hysterectomy use hormone therapy more frequently than do women with an intact uterus (58.7% vs 19.6%).\textsuperscript{140}
BMD should be measured in women older than 65 years and in women younger than 65 years with risk factors for osteoporosis. Although bone densitometry has been shown to predict fractures, at present there are no guidelines for follow-up BMD testing. However, in women with significant bone loss, repeat testing should be performed as clinically indicated.

CONCLUSIONS

During the past decade, postmenopausal hormone therapy became one of the most frequently prescribed therapies in the United States. Menopause is a natural life event, not a disease. Therefore, the decision to use hormone therapy must be individualized based on the severity of menopausal symptoms, risk of osteoporosis, and consideration of factors such as cardiovascular disease, breast cancer, and thromboembolism (Table 91–7).

Quality of evidence: 1, evidence from more than one properly randomized controlled trial; 2, evidence from more than one well-designed clinical trial with randomization from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert communities.

*Strength of recommendations: A, good evidence to support recommendation; B, moderate evidence to support recommendation; C, poor evidence to support recommendation.

Large prospective, randomized trials have shown that postmenopausal hormone therapy prescribed for disease prevention may cause more harm than good.17,58 The WHI trial reported increased risk of cardiovascular disease, breast cancer, stroke, and thromboembolic disease among women using continuous combined therapy with CEE plus medroxyprogesterone acetate compared with placebo. In the estrogen-alone arm of the study, CEE had no effect on cardiovascular disease or breast cancer risk compared to placebo, but an increased risk of stroke and thromboembolic disease was noted in those who received estrogen. The WHI trial also demonstrated that quality of life and cognition were no better in the group receiving hormone therapy than in the placebo group, and that hormone therapy increases dementia risk in women 65 years or older.

Postmenopausal symptoms, such as hot flushes and vaginal dryness, remain a valid indication for hormone therapy in the absence of contraindications. For short-term use of hormone therapy for relief of menopausal symptoms, the benefits for many women outweigh the risks. For symptoms of genital atrophy alone, local estrogen and/or nonhormonal lubricants should be considered.

Long-term use of hormone therapy cannot be recommended routinely for osteoporosis prevention given the availability of alternative therapies, such as bisphosphonates and raloxifene. For long-term hormone therapy use, the potential harm (cardiovascular disease, breast cancer, and thromboembolism) outweighs the potential benefits. Hormone therapy should not be used for prevention of CHD. Women with cardiovascular risk factors (e.g., hypertension, lipid abnormalities) can benefit from reduction of these risk factors through interventions such as weight loss, lipid-lowering therapy, use of aspirin, and physical activity.

### PRIMARY OVARIAN INSUFFICIENCY AND PREMENOPAUSAL HORMONE REPLACEMENT THERAPY

Primary ovarian insufficiency is a condition characterized by sex steroid deficiency, amenorrhea, and infertility in women younger than 40 years.143 Primary ovarian insufficiency was once considered irreversible and was described as “premature menopause” and the condition is still referred to as prematurity ovulation failure. However, primary ovarian insufficiency is not an early, natural menopause. Normal menopause results from ovarian follicle depletion, whereas primary ovarian insufficiency is characterized by intermittent ovarian function in half of affected women.141 These women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. Pregnancies have occurred in 5% to 10% of women after the diagnosis of premature ovarian failure, even in women with no follicles observed on ovarian biopsy.

### EPIDEMIOLOGY

The prevalence of primary ovarian insufficiency increases with increasing age, reaching approximately 1% of women by age 40 years.142

### ETIOPATHOLOGY

A number of physiologic or metabolic abnormalities can lead to primary ovarian insufficiency (Table 91–8). In most cases, the etiology cannot be identified.

### PATHOPHYSIOLOGY

Primary ovarian insufficiency may occur as a result of ovarian follicle dysfunction or ovarian follicle depletion and may present as either primary amenorrhea (absence of menstruation in a girl who...
Etiology of Primary Ovarian Insufficiency

Autoimmunity: (A) isolated autoimmune primary ovarian insufficiency or (B) as a component of an autoimmune polyglandular syndrome in association with Addison's disease, hypothyroidism, hypoparathyroidism, or mucocutaneous candidiasis

Iatrogenic: Chemotherapy, radiation, extensive ovarian surgery

X-chromosome abnormalities

Gonadotropin and gonadotropin-receptor abnormalities: Signal defects

Enzyme deficiencies: Cholesterol desmolase, 17α-hydroxylase, 17, 20-desmolase

Galactosemia

Blepharophimosis, ptosis, and epicanthus inversus syndrome type 1: Rare autosomal dominant syndrome in which primary ovarian insufficiency is the predominant syndrome

Perrault syndrome: Familial autosomal recessive primary ovarian insufficiency in association with deafness

Clinical Presentation

No characteristic menstrual pattern or history precedes primary ovarian insufficiency. Approximately 50% of patients with this condition have a history of oligomenorrhea or dysfunctional uterine bleeding (prolonged premature ovarian failure), and approximately 25% develop amenorrhea acutely. Some patients develop amenorrhea postpartum, whereas others experience amenorrhea after discontinuing oral contraceptives. Primary amenorrhea is not associated with symptoms of estrogen deficiency. In cases of secondary amenorrhea, symptoms may include hot flushes, night sweats, fatigue, and mood changes. Progesteronal primary ovarian insufficiency may present with hot flushes even in women who menstruate regularly. Incomplete development of secondary sex characteristics may occur in women with primary amenorrhea, whereas these characteristics typically are normal in women with secondary amenorrhea. In general, women with primary ovarian insufficiency have normal fertility before the disorder develops.

Primary ovarian insufficiency is defined by the presence of at least 4 months of amenorrhea and at least two serum FSH concentrations measuring greater than 40 milliinternational units/mL (40 IU/L) (obtained at least 1 month apart) in women younger than 40 years. A complete history should be taken, considering other factors that can affect ovarian function such as prior ovarian surgery, chemotherapy, radiation, and autoimmune disorders. In patients with primary amenorrhea, particular attention should be paid to breast and pubic hair development according to Tanner stages. Short stature, stigma of Turner syndrome, and other dysmorphic features of gonadal dysgenesis should be considered. Ideally, a pelvic exam is performed but is not always clinically appropriate. Alternatively, transabdominal ultrasonography can be performed in patients with primary amenorrhea to confirm the presence of normal anatomic structures. In the majority of cases, physical examination is completely normal. A karyotype should be performed in all patients experiencing primary ovarian insufficiency. Women with ovarian insufficiency and a karyotype containing a Y chromosome should undergo bilateral gonadectomy because of substantial risk for gonadal germ cell neoplasia. Ovarian biopsy and antiiovarian antibody testing are investigational procedures with no proven clinical benefit in primary ovarian insufficiency. As clinically indicated, the workup should include tests for the diagnosis of other possible associated autoimmune disorders, such as hypothyroidism, diabetes mellitus, and Addison's disease.

In the majority of patients, ovarian insufficiency develops after the establishment of regular menses. Young women with primary ovarian insufficiency who develop ovarian dysfunction before they achieve peak adult bone mass sustain sex steroid deficiency for more years than do naturally menopausal women. This deficiency can result in a significantly higher risk for osteoporosis and cardiovascular disease. Importantly, a survey of more than 19,000 women between the ages of 25 and 100 years suggests that ovarian insufficiency occurring before age 40 years is associated with significantly increased mortality, with an age-adjusted odds ratio for all-cause mortality of 2.14 (95% CI 1.15–3.99).

Young women find the diagnosis of primary ovarian insufficiency particularly traumatic and frequently need extensive emotional and psychological support. Although most of these women will, in fact, be infertile, it is important to emphasize that primary ovarian insufficiency can be transient and that spontaneous pregnancies have occurred even years after diagnosis.

Treatment

Results from randomized trials of hormone therapy in postmenopausal women cannot be extrapolated to premenopausal women with ovarian dysfunction. Postmenopausal women who take hormone therapy prolong their exposure to estrogen beyond the average age of completion of their reproductive phase. In contrast, women with primary ovarian insufficiency need exogenous sex steroids to compensate for the decreased production by their ovaries. Importantly, 47% of young women with primary ovarian insufficiency have significantly reduced BMD within 1.5 years of their diagnosis despite taking standard hormone therapy.

Desired Outcome

The goal of therapy in young women with primary ovarian insufficiency is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary.
**GENERAL APPROACH TO TREATMENT**

Hormone therapy with estrogen, progestogen, and testosterone is used and generally should be continued until the average age of natural menopause.

**PHARMACOLOGIC THERAPY**

Optimal hormone therapy depends on whether the patient has primary or secondary amenorrhea. Young women with primary amenorrhea in whom secondary sex characteristics have failed to develop initially should be given very low doses of estrogen in an attempt to mimic the gradual pubertal maturation process. A typical regimen is 0.3 mg CEE unopposed (i.e., no progestogen) daily for 6 months, with incremental dose increases at 6-month intervals until the required maintenance dose is achieved. Gradual dose escalation often results in optimal breast development and allows time for the young woman to adjust psychologically to her physical maturation. Cyclic progestogen therapy, given 12 to 14 days per month, should be instituted toward the end of the second year of treatment.

Women with secondary amenorrhea who have been estrogen deficient for 12 months or longer also should be given low-dose estrogen replacement initially to avoid adverse effects such as mastalgia and nausea. However, the dose can be titrated up to maintenance levels over a 6-month period, and progestogen therapy can be instituted with the initiation of estrogen therapy. Women with a brief history of secondary amenorrhea are less likely to experience undesired effects from hormone therapy if they are given a reduced dose for the first month of therapy, followed by a full dose from the second month onward.

An estrogen dose equivalent to at least 1.25 mg CEE (or 100 mcg transdermal estradiol) is needed to achieve adequate estrogen replacement in young women. A progestogen should be given for 12 to 14 days per calendar month to prevent endometrial hyperplasia (Table 91–9). Estrogens given in usual replacement doses do not suppress spontaneous follicular activity or ovulation. Because women with primary ovarian insufficiency can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns (i.e., only cyclic regimens should be used). Patients who miss an expected menses should be tested for pregnancy and should discontinue hormone therapy. Because most young women negatively associate hormone therapy with menopause in older women, some clinicians prefer to prescribe oral contraceptives for hormone replacement in premenopausal women with hypogonadism. However, oral contraceptives may not inhibit ovulation or effectively prevent pregnancy in young women with elevated gonadotropin levels.

Women with primary ovarian insufficiency have testosterone deficiency. In these young women, testosterone replacement, in addition to estrogen, may be important. However, preliminary analysis of a prospective study at the National Institutes of Health suggests that long-term “physiologic” testosterone supplementation (150 mcg/day), in addition to standard hormone replacement, did not significantly improve BMD and sexual function in these young women.

Importantly, all women with primary ovarian insufficiency should understand that hormone therapy generally should be continued until the average age of natural menopause and that long-term follow-up is necessary.

**Pharmacoeconomic Considerations**

Depending on the duration of therapy, the cost of therapy for primary ovarian insufficiency may be more or less than that associated with therapy for menopausal symptoms. The cost of therapy can be substantial for women who undergo fertility testing and treatment prior to receiving the diagnosis of primary ovarian insufficiency.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Similar to the treatment of menopause, an assessment of the efficacy of hormone therapy, and its accompanying risks, should be performed on a regular basis. Young women with primary ovarian insufficiency should be monitored annually for their response to treatment, and their adherence with hormone therapy should be assessed regularly. Patients should be evaluated continuously for the presence of signs and symptoms of associated autoimmune endocrine disorders, such as hypothyroidism, adrenal insufficiency, and diabetes mellitus. Baseline BMD testing should be performed in all women with primary ovarian insufficiency. Mammography should be performed annually after age 40 years in accordance with accepted guidelines. Additional mammography screening in premenopausal women younger than 40 years who are receiving physiologic hormone therapy is not warranted. Other tests should be performed as clinically indicated.

**CONCLUSIONS**

Approximately 1% of women spontaneously develop ovarian insufficiency before age 40 years. Primary ovarian insufficiency is not an early natural menopause. Most affected women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. However, these women sustain sex steroid deficiency for more years than do naturally menopausal women, resulting in a significantly higher risk for osteoporosis and cardiovascular disease.

Women with primary ovarian insufficiency need exogenous sex steroids to compensate for the decreased production by their ovaries. Thus, premenopausal hormone therapy is required at least until these women reach the age of natural menopause.

The goal of therapy is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary. This usually requires the administration of estrogen at a dose greater than the standard dose given to older women experiencing natural menopause.
Because women with primary ovarian insufficiency can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns. Patients who miss an expected menses should be tested for pregnancy and, if positive, the hormone therapy should be promptly discontinued.

Annual follow-up should include assessment of adherence with the prescribed hormone therapy regimen and evaluation for signs and symptoms of associated endocrine disorders.

CHAPTER 92
Erectile Dysfunction

MARY LEE

KEY CONCEPTS

1. The incidence of erectile dysfunction is low in men younger than 40 years of age. The incidence increases as men age, likely as a result of concurrent medical conditions that impair the vascular, neurologic, psychogenic, and hormonal systems necessary for a normal penile erection.

2. Many commonly used drugs have sympatholytic, anticholinergic, sedative, or antiandrogenic effects that may exacerbate or contribute to the development of erectile dysfunction. Clinicians should be familiar with these agents and be prepared to make adjustments in drug regimens to minimize adverse effects of these drugs on a patient's erectile function.

3. The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse the underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, and chronic ethanol abuse, should be addressed and minimized.

4. Specific treatments for erectile dysfunction include vacuum erection devices, pharmacologic treatments, psychotherapy, and surgery.

5. The ideal treatment of erectile dysfunction should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions.

6. Specific treatment is first initiated with the least invasive forms of treatment, including vacuum erection devices or oral phosphodiesterase inhibitors, followed by intracavernosal injections or intraurethral inserts, and finally by surgical insertion of a penile prosthesis.

7. Vacuum erection devices can have a slow onset of action (30 minutes) and are not discreet; therefore, they are most effective for a couple in a stable relationship.

8. Although phosphodiesterase inhibitors are convenient and effective regardless of the etiology of erectile dysfunction, they fail in 30% to 40% of patients. Also, phosphodiesterase inhibitors are contraindicated in patients taking any dosage formulation of nitrate.

9. Testosterone supplementation should be reserved for patients with primary or secondary hypogonadism who have erectile dysfunction as a consequence of a decreased libido. Testosterone supplementation should not be used by patients with erectile dysfunction who have normal serum testosterone levels.

10. Although intracavernosal injections and intraurethral pellets of alprostadil are effective independent of the etiology of erectile dysfunction, they fail in one third of patients. To self-administer medication by these routes, patients require training to minimize administration-related adverse effects.

The National Institutes of Health Consensus Development Panel on Impotence defines erectile dysfunction as the failure to achieve a penile erection to allow for satisfactory sexual intercourse. Patients may refer to it as impotence. Erectile dysfunction must be distinguished from disorders of libido, ejaculatory disorders, and infertility, which are caused by different pathophysiologic mechanisms and are treated with alternative agents (Table 92–1). A patient may suffer from one or more disorders of sexual dysfunction. For example, an elderly man with primary hypogonadism may suffer from decreased libido and erectile dysfunction. Diagnosis of the type of sexual disorder that a patient has is a key to initiating the most appropriate treatment.

EPIDEMIOLOGY

1. The incidence of erectile dysfunction is low in men younger than 40 years of age but increases as men age. The Massachusetts Male Aging Study, a cross-sectional survey of a random sample of 1,290 men in the Boston area, was conducted during the period...
Urologic Disorders

SECTION 10

arteriosclerosis, hyperlipidemia, diabetes mellitus, or psychiatric
disorders) or from medications that patients may be taking for these
diseases. 2–5 For example, up to 50% of patients with diabetes melli-
tus develop erectile dysfunction, and medications such as β-blockers
are associated with a high incidence of erectile dysfunction.

PHYSIOLOGY OF A NORMAL PENILE ERECTION

A normal penile erection requires full functioning of several physi-
ologic systems: vascular, nervous, and hormonal. The patient also
must be psychologically receptive to sexual stimuli.

VAScular SYSTEM

The penis comprises two corpora cavernosa on the dorsal side and
one corpus spongiosum on the ventral side. The corpus spongiosum
surrounds the urethra and forms the glans penis. The corpora are
composed of multiple interconnected sinuses, which can fill with
blood to produce an erection. The corpora cavernosa are encased
by the tunica albuginea, a fibrous tissue membrane, which has lim-
ited distensibility. In the flaccid state, arterial flow into and venous
outflow from the corpora are balanced. During the erectile phase,
arterial blood flow increases and blood fills the sinusoids within the
corpora, which causes penile swelling and elongation. The erection
is prolonged by a decrease in venous outflow from the corpora,
which is caused by compression of subtunical venules against the
tunica albuginea by the swollen corpora (Fig. 92–1).

from 1987 to 1989. The study reported an overall prevalence of 52%
for any degree of erectile dysfunction in men aged 40 to 70 years,
with an age-related increase in incidence ranging from 12.4% in
men aged 40 to 49 years, up to 46.4% in men aged 60 to 69 years. 1,2
In the more recent Health Professional Follow-Up Study of more
than 31,000 male health professionals aged 53 to 90 years, the preva-
ience of erectile dysfunction was 33%. 3 Interestingly, although the
prevalence of erectile dysfunction increases with patient age, many
patients fail to seek medical treatment. 4

Erectile dysfunction is sometimes assumed to be a symptom of the aging process in men. However, more likely it results from concurrent medical conditions of the patient (e.g., hypertension,

![FIGURE 92-1. Microanatomy of and vascular changes in the penis in flaccid and erect states. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, causing penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules by the swollen corpora. (From Walsh PC, ed. Campbell’s Urology, 8th ed. Philadelphia, PA: WB Saunders, 2002:1595, 1697.)](image-url)
Arterial flow into the corpora is enhanced by acetylcholine-mediated vasodilation. Acetylcholine indirectly enhances arterial flow to the corpora and increases sinusoidal filling of the corporal tissue. That is, acetylcholine is a conotoxinmitter, which works along with other nonadrenergic noncholinergic—containing cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), or vasoactive intestinal polypeptide—to produce vasodilation. In effect, cGMP and cAMP are secondary messengers that direct desired effects in target tissues. Acetylcholine produces an erection probably through two different pathways. Through one pathway, in the presence of sexual stimulation to genital tissue, acetylcholine enhances the production of nitric oxide by endothelial cells and nonadrenergic noncholinergic neurons. Nitric oxide enhances the activity of guanylate cyclase, which increases the conversion of cyclic guanosine triphosphate to cGMP. cGMP decreases intracellular calcium concentrations in smooth muscle cells of penile arteries and cavernosal sinuses. As a result, smooth muscle relaxation occurs, which enhances arterial blood flow to and blood filling of the corpora. An erection results.

In an alternative pathway, acetylcholine or prostaglandin E enhances the activity of adenyl cyclase, which increases the conversion of cyclic adenosine triphosphate to cAMP, a potent muscle relaxant. Similar to cGMP, cAMP decreases intracellular calcium concentrations to produce smooth muscle relaxation in cells of the arteries and cavernosal sinuses. Arterial blood flow to and blood filling of the corpora are enhanced, and a penile erection results.

**NERVOUS SYSTEM AND PSYCHOGENIC STIMULI**

Some erections are mediated by a sacral nerve reflex arc (e.g., erections can occur while the patient is sleeping). However, in the conscious patient, sensory sexual stimulation mediates erections via the central nervous system. That is, when a patient sees an attractive partner, hears sweet words, smells a particular scent, or tastes or touches a pleasant object, these situations can result in an erection. In this case, the patient’s brain processes this information and the nervous impulse is carried down the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora, resulting in an erection.

The medial preoptic area of the hypothalamus is thought to be that portion of the brain responsible for integrating external stimuli. Here dopamine exerts a proerectogenic effect, whereas, α₂-adrenergic stimulation causes the penis to become and/or remain flaccid. After moving down the spinal cord, nerve impulses travel to the penis by efferent peripheral nerves, including inhibitory sympathetic neurons (T11–L2), proerectogenic parasympathetic neurons (S2–S4), and proerectogenic somatic neurons (S2–S4).

In summary, acetylcholine produces an erection by working along with other conotoxinmitters, including cGMP and cAMP. Thus, an erection is mediated neurologically, maintained by arterial blood filling of the corpora, and sustained by occlusion of venous outflow from the corpora.

Detumescence, or the progression of an erect penis to a flaccid state, results from the actions of norepinephrine, which contracts vascular smooth muscle to decrease arterial inflow to the corpora and contracts sinusoidal tissue in the corpora. As a result, venous outflow from the corpora increases.

**HORMONAL SYSTEM**

Testosterone is principally produced by the testes at a daily rate of 4 to 8 mg. Production follows a circadian pattern with highest blood levels in the morning and lowest levels in the evening. Physiologically active (free) testosterone comprises only 2% of circulating blood levels. About 50% to 60% of testosterone in the bloodstream is tightly bound to sex hormone-binding globulin and is inactive. The rest of circulating testosterone is reversibly bound to albumin; this portion of testosterone is in equilibrium with the free fraction.

Testosterone stimulates libido (sexual drive) and increases muscle mass in males. In some target cells with 5-alpha reductase, testosterone is activated to dihydrotestosterone. Dihydrotestosterone, which is more potent than testosterone, stimulates prostate gland growth, increases facial and body hair, induces baldness, and causes acne. In adipose tissue, a small portion of testosterone is converted to estradiol which can lead to gynecomastia.

Beginning at age 40 years, men experience a gradual decrease in testicular production of testosterone, with an associated decrease in muscle mass and sexual function. The Massachusetts Male Aging Study reported that 6% to 12% of elderly males had symptoms of hypogonadism. Within the normal physiologic serum total testosterone concentration range (normal, 300–1,100 ng/dL; 10.4–38.2 nmol/L), sexual drive is usually normal. However, because of variability in circulating levels of sex hormone binding globulin, a patient’s serum concentration of testosterone should always be interpreted in the context of the patient’s symptoms and physical examination findings. To confirm hypogonadism when the serum total testosterone concentration is equivocal, the clinician should obtain a serum free (bioavailable) testosterone level.

The relationship between erectile dysfunction and serum testosterone levels is complicated. Patients with normal serum testosterone levels may have erectile dysfunction, and patients with subnormal serum testosterone levels may have normal sexual function. When a patient has hypogonadism and libido is decreased, a patient may not develop erections. In this case, erectile dysfunction is considered secondary to a decreased libido.

**PATHOPHYSIOLOGY**

Erectile dysfunction can result from any single abnormality or combination of abnormalities of the four systems necessary for a normal penile erection. Vascular, neurologic, or hormonal etiologies of erectile dysfunction are collectively referred to as organ erectile dysfunction. Approximately 80% of patients with erectile dysfunction have the organic type. Patients who do not respond to psychogenic stimuli have psychogenic erectile dysfunction.

Diseases that compromise vascular flow to the corpora cavernosum (e.g., peripheral vascular disease, arteriosclerosis, and essential hypertension) are associated with an increased incidence of erectile dysfunction. Diseases that impair nerve conduction to the brain (e.g., spinal cord injury or stroke) or conditions that impair peripheral nerve conduction to the penile vasculature (e.g., diabetes mellitus) can result in erectile dysfunction.

Diseases associated with hypogonadism, primary or secondary, result in subphysiologic levels of testosterone, which cause diminished sexual drive (decreased libido) and secondary erectile dysfunction. Primary hypogonadism can be associated with the normal aging process in men or surgical removal of the testes for treatment of prostate or testicular cancer. Secondary hypogonadism may result from hypothalamic or pituitary disorders of luteinizing hormone–releasing hormone or luteinizing hormone, respectively; or elevated prolactin levels, which can result from pituitary tumors or can occur in patients with chronic renal failure.

Patients must be in the proper mental frame of mind to be receptive to sexual stimuli. Patients who suffer from malaise, have
reactive depression or performance anxiety, are sedated, have Alzheimer disease, have hypothyroidism, or have mental disorders, commonly complain of erectile dysfunction. In most studies, patients with psychogenic erectile dysfunction generally exhibit a higher response rate to various interventions than do patients with organic erectile dysfunction because the former have less severe disease.

Social habits of patients have been linked to erectile dysfunction. The vasoconstrictor effect of cigarette smoking may compromise blood flow to the corpora and decrease cavernosal filling. Excessive alcohol intake may lead to androgen deficiency, peripheral neuropathy, or chronic liver disease, all of which can contribute to erectile dysfunction.

Medications may cause erectile dysfunction through similar pathophysiologic mechanisms (Table 92–2).8–11 Medications are estimated to be responsible for approximately 10% to 25% of cases of erectile dysfunction.

### CLINICAL PRESENTATION: ERECTILE DYSFUNCTION

#### General
- Men are affected emotionally in many different ways
- Depression
- Performance anxiety
- Marital difficulties and avoidance of sexual intimacy (patients are often brought to a physician by their partners)
- Nonadherence to medications patient believes are causing erectile dysfunction

#### Symptoms
- Erectile dysfunction or inability to have sexual intercourse

#### Signs
- If completing an International Index of Erectile Dysfunction survey, results are consistent with low satisfaction with the quality of erectile function.
- Medical history may identify concurrent medical illnesses, past surgical procedures that interfere with good vascular flow to the penis or damage nerve function to the corpora, or mental disorders associated with decreased reception of sexual stimuli.
- Medication history may reveal prescription or nonprescription medications that could cause erectile dysfunction.
- Physical examination may reveal signs of hypogonadism (e.g., gynecomastia, small testicles, decreased body hair or beard, decreased muscle mass), which may contribute to erectile dysfunction. The patient may have an abnormally curved penis when erect, decreased pulses in the pelvic region (suggesting impaired vascular flow to the penis), or decreased anal sphincter tone (suggesting impaired nerve function to the corpora). Men older than 50 years should undergo a digital rectal examination to determine whether an enlarged prostate is contributing to the patient’s erectile dysfunction.

#### Laboratory Tests
- If patient has signs of hypogonadism and complains of decreased libido, a serum testosterone concentration may be
below the normal range, which would be consistent with a hormonal cause of erectile dysfunction.
- If the patient has an enlarged prostate noted on digital rectal examination, a blood sample for prostate specific antigen should be obtained. If elevated, the patient should be evaluated for a prostate disorder, which could contribute to erectile dysfunction.

### DIAGNOSIS

With the availability in the late 1990s of effective medications for erectile dysfunction independent of the etiology, diagnostic evaluation of erectile dysfunction became streamlined. Key assessments include a description of the severity of erectile dysfunction, complete medical and surgical histories, review of concurrent medications, physical examination, and selected clinical laboratory tests.

To assess the severity of erectile dysfunction, the patient should be asked about the quality of sexual intercourse for the last 4 weeks to 6 months. A self-administered standardized questionnaire, such as the International Index of Erectile Dysfunction (IIEF), is often used. It is administered before initiation of any treatment and repeated at regular intervals during treatment. It includes 15 questions about the quality of erectile function and satisfactoriness of sexual intercourse. Questions include the following: How often were you able to maintain an erection? How difficult was it to sustain an erection? How satisfied are you with your sexual life? The physician should carefully assess the expectations for erectile function of the patient and the partner to ensure that expectations are reasonable. Shorter versions of the IIEF and other self-reporting questionnaires are also used in clinical practice.

A medical history should be obtained to identify concurrent medical illnesses (e.g., hypertension, atherosclerosis, hyperlipidemia, diabetes mellitus, depression) or surgical procedures (e.g., perineal or pelvic) that are risk factors for or are associated with organic or psychogenic erectile dysfunction. Underlying diseases that do not optimally respond to treatment should be addressed before specific treatment for erectile dysfunction is initiated. If the patient smokes cigarettes, drinks excessive amounts of ethanol, or uses recreational drugs, these social habits should be discontinued before specific treatment for erectile dysfunction is started.

A complete listing of the patient’s prescription and nonprescription medications and dietary supplements should be reviewed by the clinician, who should identify drugs that may be contributing to erectile dysfunction. If possible, causative agents should be discontinued or the dose should be reduced.

A physical examination of the patient should include a check for hypogonadism (i.e., signs of gynecomastia, small testicles, and decreased beard or body hair). The penis should be evaluated for diseases associated with abnormal penile curvature (e.g., Peyronie disease), which are associated with erectile dysfunction. Femoral and lower extremity pulses should be assessed to provide an indication of vascular supply to the genitals. Anal sphincter tone and other genital reflexes should be checked for the integrity of the nerve supply to the penis. A digital rectal examination in patients 50 years or older is needed to rule out benign prostatic hyperplasia, which may contribute to erectile dysfunction.

Selected laboratory tests should be obtained to identify the presence of underlying diseases that could cause erectile dysfunction. They include a fasting serum blood glucose and lipid profile. Serum testosterone levels should be checked in patients older than 50 years and in younger patients who complain of decreased libido. At least two serial early morning serum testosterone levels are needed to confirm the presence of hypogonadism.

Finally, erectile dysfunction is a potential marker for arteriosclerosis. Therefore, patients who present with erectile dysfunction should undergo a cardiovascular risk assessment to identify treatable medical conditions.

### TREATMENT

#### Erectile Dysfunction

**DESIRE OUTCOMES**

The goal of treatment is improvement in the quantity and quality of penile erections suitable for satisfactory intercourse. Simple as this may sound, healthcare providers must ensure that patients and their partners have reasonable expectations for any therapies that are initiated. Furthermore, only patients with erectile dysfunction should be treated. Patients who have normal sexual function should not seek—or be encouraged to seek—treatment in an effort to enhance sexual function or enable increased activity.

**GENERAL APPROACH TO TREATMENT**

**The Second Princeton Consensus Conference** is a widely accepted multidisciplinary approach to managing erectile dysfunction that maps out a stepwise treatment plan. The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, or chronic ethanol abuse, should be addressed and minimized. Patients should follow a heart-healthy lifestyle, which includes physical fitness, weight loss to achieve a normal body mass index, low cholesterol diets, no excessive ethanol intake, and no smoking. In some cases, these types of interventions are sufficient to restore erectile function. However, if erectile dysfunction does not respond to these measures, specific treatment is indicated.

For patients with psychogenic erectile dysfunction, psychotherapy can be used as monotherapy or as an adjunct to specific treatments for the disorder. To enhance the relevance of psychotherapy, both the patient and the partner should be included in the counseling sessions. Treatment should be individualized and should address immediate factors that may be causing performance anxiety or depression. The effectiveness of psychotherapy is generally low, and long-term psychotherapy is often necessary.

Specific treatments of erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, and surgery. The ideal treatment of this disorder should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions (Table 92–3). Generally, when choosing from among treatment approaches, those that are least invasive are selected first; more invasive therapies are reserved for patients who do not respond to first-line agents.

The American Urological Association Guideline on the Management of Erectile Dysfunction clearly identifies oral phosphodiesterase inhibitors for first-line treatment. Vacuum erection devices, intracavernosal injection of erecogenic agents, or intraurethral prostaglandin inserts are second-line treatments; prescribing of a particular agent for a patient should be individualized. Surgical intervention should be reserved for patients who fail to respond to first- and second-line treatments. A sample algorithm that guides selection of treatment is shown in Figure 92–2.

FIGURE 92-2. Algorithm for selecting treatment for erectile dysfunction. For organic erectile dysfunction (ED), oral agents are first-line therapy for younger patients, and vacuum erection devices are generally used first in older patients who are married or otherwise have a stable sexual relationship. These two approaches are sometimes used together in an effort to avoid surgical implantation of penile prostheses.
**CHAPTER 92**

---

**PHOSPHODIESTERASE INHIBITORS**

**Mechanism**

In the presence of sexual stimulation, nitric oxide is released by neurons or endothelial cells in penile tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for conversion of guanylate triphosphate to cGMP (Fig. 92–4).

CgMP is a vasodilatory secondary messenger that upregulates the response to nitric oxide, increases smooth muscle relaxation, enhances arterial flow to the corpora cavernosa and enhances blood filling of cavernosal sinuses. Catabolism of cGMP is mediated by phosphodiesterase.

Three competitive, reversible inhibitors of the phosphodiesterase isoenzyme type 5 found in genital tissue are marketed for erectile dysfunction in the United States (Table 92–4). They act by decreasing catabolism of cGMP. However, phosphodiesterase isoenzyme type 5 is also found in peripheral vascular tissue, tracheal smooth muscle, and platelets. Inhibition of phosphodiesterase in these non-genital tissues can produce unwanted effects.

The three marketed phosphodiesterase inhibitors differ in their degree of selectivity in inhibiting other phosphodiesterase isoenzymes, pharmacokinetic profiles, drug–food interactions, and adverse effects (see Table 92–4).

**Efficacy**

Because of their apparent effectiveness, convenient route of administration, and comparatively low incidence of serious adverse effects, phosphodiesterase inhibitors are considered first-line therapy for erectile dysfunction, particularly in younger patients. They allow for discreet use. Although not based on direct comparison trials, all three commercially available phosphodiesterase inhibitors are considered to be equally effective.

In the presence of sexual stimulation and in doses of 25 to 100 mg, sildenafil produces satisfactory erections in 56% to 82% of patients, independent of the etiology of erectile dysfunction. Similar results are documented in the product labeling for the other two agents in this class (65%–80% for vardenafil and 62%–77% for tadalafil). Response rates in the lower range for phosphodiesterase inhibitors have been documented in patients with diabetes mellitus or in patients after radical prostatectomy, probably due to neuropathy or surgery-related nerve damage, respectively. The effectiveness of the drugs appears to be dose related.

Approximately 30% to 40% of patients do not respond to phosphodiesterase inhibitors. At least half of nonresponders can only. These have safety mechanisms that minimize the likelihood of excessively high vacuum pressures which can cause penile discomfort and injury.

Pain or injury from VEDs most often is caused by the constriction bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the constriction bands are applied for longer than 30 to 60 minutes, the penile shaft may turn blue and hurt. Patients may complain that a hinge-like erection is produced in that the penis pivots on the rubber ring or tension band. Patients sometimes fail to ejaculate.

VEDs are contraindicated in patients with sickle cell disease. These patients are prone to priapism, which can be exacerbated by the use of constriction bands with VEDs. The devices also should be used cautiously by patients taking oral anticoagulants because warfarin, through a poorly understood and idiosyncratic mechanism, can cause priapism.

---

**VACUUM ERECTION DEVICE**

A VED has three parts: a pump, which generates a negative vacuum pressure; a cylinder, which is closed at one end and into which the penis is inserted; and tubing, which connects the pump to the cylinder. The patient inserts his penis into the open end of the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. Then the patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient can use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and reduce venous outflow from the penis. With the assistance of loading cones to protect the glans, these bands or rings can be rolled over the glans penis and up the erect penile shaft. Alternatively, they can be first threaded onto the plastic cylinder before the penis is inserted. Once the penis is erect, the band or ring can be rolled off the cylinder onto the base of the penis (Fig. 92–3).

The onset of action of the VED is comparatively slow (30 minutes), which requires patience from both the patient and the sexual partner. VEDs are not discreet. That is, a patient’s use of a VED is evident to the partner. For this reason, VEDs appear to work best in older patients who are married or who have stable sexual relationships. In this group, VEDs could be considered first-line therapy, and the overall satisfaction rate can be as high as 60% to 80%. However, 6% to 11% of partners complain that the penis is cool to the touch or is discolored (bluish) in appearance, particularly when constriction bands are used.

VEDs may be used as second-line therapy in patients who do not respond to oral or injectable drug treatments for erectile dysfunction. The combination of a VED with intracavernosal or intraurethral alprostadil is associated with a higher efficacy rate than use of the VED alone. As a result, combination therapy sometimes is attempted before penile prosthesis surgery is considered in the patient who fails VED monotherapy.

VEDs are available with manual or battery-operated pumps. The latter offer greater convenience, particularly in patients with arthritis of the hands, who find manual pumps too difficult and tiring to operate. The American Urological Association recommends the use of commercially available VEDs by prescription only. These have safety mechanisms that minimize the likelihood of excessively high vacuum pressures which can cause penile discomfort and injury.

Pain or injury from VEDs most often is caused by the constriction bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the constriction bands are applied for longer than 30 to 60 minutes, the penile shaft may turn blue and hurt. Patients may complain that a hinge-like erection is produced in that the penis pivots on the rubber ring or tension band. Patients sometimes fail to ejaculate.

VEDs are contraindicated in patients with sickle cell disease. These patients are prone to priapism, which can be exacerbated by the use of constriction bands with VEDs. The devices also should be used cautiously by patients taking oral anticoagulants because warfarin, through a poorly understood and idiosyncratic mechanism, can cause priapism.

**Mechanism**

In the presence of sexual stimulation, nitric oxide is released by neurons or endothelial cells in penile tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for conversion of guanylate triphosphate to cGMP (Fig. 92–4).

CgMP is a vasodilatory secondary messenger that upregulates the response to nitric oxide, increases smooth muscle relaxation, enhances arterial flow to the corpora cavernosa and enhances blood filling of cavernosal sinuses. Catabolism of cGMP is mediated by phosphodiesterase.

Three competitive, reversible inhibitors of the phosphodiesterase isoenzyme type 5 found in genital tissue are marketed for erectile dysfunction in the United States (Table 92–4). They act by decreasing catabolism of cGMP. However, phosphodiesterase isoenzyme type 5 is also found in peripheral vascular tissue, tracheal smooth muscle, and platelets. Inhibition of phosphodiesterase in these non-genital tissues can produce unwanted effects.

The three marketed phosphodiesterase inhibitors differ in their degree of selectivity in inhibiting other phosphodiesterase isoenzymes, pharmacokinetic profiles, drug–food interactions, and adverse effects (see Table 92–4).
In addition, treatment of concomitant medical illnesses which contribute to erectile dysfunction (e.g., diabetes mellitus, hypertension, hypogonadism) should be optimized. 20 The effectiveness of switching from one phosphodiesterase inhibitor to another when the patient does not respond to an initial agent is controversial. In two small studies, vardenafil was beneficial in patients who did not respond to sildenafil. 26, 29 However, controlled clinical trials in larger patient groups are needed before this strategy is used as routine treatment.

The phosphodiesterase inhibitors should not be used by patients with normal erectile function. Also, according to Food and Drug Administration (FDA)–approved labeling, the drugs should not be used in combination with other forms of therapy for erectile dysfunction because prolonged erections (which may lead to priapism) may result. 30 Long-term use of phosphodiesterase inhibitors is not associated with tachyphylaxis. 31, 32

*Sildenafil doses should be decreased when any potent cytochrome P450 3A4 inhibitor (e.g., cimetidine, erythromycin, clarithromycin, ketoconazole,itraconazole, ritonavir, and saquinavir) is used. Vardenafil doses vary according to the agent used (2.5 mg every 72 hours for ritonavir; 2.5 mg every 24 hours for indinavir, ketoconazole 400 mg daily, and itraconazole 400 mg daily; and 5 mg every 24 hours for ketoconazole 200 mg daily, itraconazole 200 mg daily, and erythromycin). Tadalafil doses are reduced only when the drug is used with the most potent cytochrome P450 3A4 inhibitors (e.g., ketoconazole,ritonavir). PDE, phosphodiesterase.
More than 25 different phosphodiesterase isoenzymes have been identified; however, the physiologic effects of stimulation and inhibition of some of these isoenzymes remain to be elucidated. Of note, phosphodiesterase isoenzyme type 6 is localized to the rods and cones of the eye. Inhibition of this isoenzyme has been associated with blurred vision and cyanopsia. Sildenafil is the most potent inhibitor of phosphodiesterase isoenzyme type 6, vardenafil is an intermediate inhibitor, and tadalafl is the least potent inhibitor. Likewise, phosphodiesterase isoenzyme type 11 is localized to striated muscle. Inhibition of this isoenzyme has been associated with myalgia and muscle pain. Tadalafil exerts the greatest inhibitory activity against phosphodiesterase type 11.

### Pharmacokinetics and Drug–Food Interactions

Pharmacokinetic parameters of the phosphodiesterase inhibitors are listed in Table 92–4.

Vardenafil and sildenafil have similar pharmacokinetic profiles. Both drugs have a 1-hour onset of action and short duration of action. Oral absorption is significantly delayed when either drug is taken within 2 hours of a fatty meal. In contrast, tadalafl has a delayed onset of action of 2 hours, has a prolonged duration of action up to 36 hours, and food does not affect its rate of absorption. Thus, tadalafl offers greater spontaneity for patients, as one dose can last through an entire weekend and allow for multiple acts of sexual intercourse over multiple days with a single dose.

The onset of action of these agents has undergone reexamination to assess how soon after drug administration patients can expect to have an erection suitable for intercourse. Although up to 50% of patients may develop an erection within 20 to 30 minutes of sildenafil 100 mg, vardenafil 20 mg, or tadalafl 20 mg, the rest of the patients may require a full hour to achieve an adequate erectile response. Therefore, patients should be instructed to allow adequate time for the drug to work.

Concomitant ingestion of ethanol with phosphodiesterase inhibitors can result in orthostatic hypotension. Therefore, the manufacturer recommends that patients avoid ethanol when taking these medications.

All three phosphodiesterase inhibitors are hepatically catabolized principally by the cytochrome P450 3A4 microsomal isoenzyme and by other P450 isoenzymes (minor routes) and/or other hepatic enzymes. Sildenafil and vardenafil have active metabolites, which are excreted primarily in the feces (see Table 92–4).

### Dosing

The usual oral doses of the phosphodiesterase inhibitors are listed in Table 92–4. Sildenafil and vardenafil should be taken on demand or at least 30 to 60 minutes before sexual intercourse. Tadalafil should be taken at least 2 hours before sexual intercourse. The durations of action for sildenafil and vardenafil are 4 to 5 hours, whereas the effects of tadalafl last for 36 hours. The agents vary as to whether doses must be adjusted for patients 65 years and older and those with compromised hepatic or renal function. Patients should be advised to take no more than the amount prescribed and to use only one dose per day (or less often in the case of some patients taking tadalafl). Doses greater than those recommended have been described in the published literature (e.g., tadalafl 100 mg); however, such dosing regimens have not consistently produced improved erectile responses.

For patients who do not respond to an adequate course of on-demand phosphodiesterase inhibitors for erectile dysfunction, daily low dosing of these agents may improve endothelial function in cavernosal tissue. That is, regular use of phosphodiesterase inhibitors may increase local concentrations of cGMP, which may lead to increased oxygen tension, improved blood flow, and reduced endothelial damage. A preliminary clinical trial of daily use of tadalafil 2.5 or 5 mg showed a 58% frequency of successful sexual intercourse compared with conventional on-demand use of tadalafl 5 to 20 mg, which produced a 21% frequency of success. Other potential advantages of daily low dosing regimens include a lower potential for dose-related adverse effects, lower cost, and increased spontaneity of sexual intercourse. However, more extensive clinical study is needed to evaluate the benefit of daily dosing of phosphodiesterase inhibitors before the approach can be preferred to an on-demand regimen.

### Adverse Effects

Most adverse effects of the phosphodiesterase inhibitors are mild or moderate and are self-limited, and patients often become tolerant to them with continued use. The rates of drug discontinuation caused by adverse effects are low, ranging from 2.1% to 2.5%, and are similar for all three agents. In usual doses the most common adverse effects are headache (11%), facial flushing (12%), dyspepsia (5%), nasal congestion (3.4%), and dizziness (3%), all of which result from vasodilation or smooth muscle relaxation secondary to inhibition of phosphodiesterase isoenzyme type 5 in extragenital tissues.

Sildenafil and vardenafil produce an 8- to 10-mm Hg decrease in systolic and a 5 to 6 mm Hg decrease in diastolic blood pressure starting approximately 1 hour after a dose is taken and lasting for 4 hours. Most patients are asymptomatic as a result of these blood pressure changes, but some patients, particularly those taking multiple antihypertensives or nitrates or those with baseline hypotension, may develop clinical symptoms as a consequence of these peripheral vascular effects. Tadalafil does not produce decreases in blood pressure, but it must be used with caution in patients with cardiovascular disease because of the cardiac risk inherent to sexual activity. A management approach for such patients, developed based on an analysis of deaths in men who were using sildenafil and commonly referred to as the recommendations of the Princeton Consensus Guideline Conference II, should be applied to all the phosphodiesterase inhibitors (Table 92–5).

Sildenafil and vardenafil cause increased sensitivity to light, blurred vision, or loss of blue–green color discrimination in 2% to 3% of patients. These effects result from inhibition of phosphodiesterase type 6 in the photoreceptor cells of the retinal rods and cones, particularly at doses larger than 100 mg. Visual adverse effects commonly occur at the time of peak serum concentrations. Although visual adverse effects are mild and reversible, caution regarding use is recommended for airplane pilots, who rely on green and blue lights for landing planes. Tadalafil has minimal to no inhibitory activity against type 6 phosphodiesterase, and no visual adverse effects have been reported. Nevertheless, according to current product labeling, all phosphodiesterase inhibitors should be used cautiously in patients at risk for retinitis pigmentosa, a genetic disease associated with retinal phosphodiesterase deficiency.

Nonarteritic anterior ischemic optic neuropathy (NAION) is a sudden, unilateral, painless blindness, which may be irreversible. Isolated cases of NAION have been associated with phosphodiesterase inhibitor use. Although a cause-and-effect relationship has not been definitively established, the blood pressure–lowering effects of these medications may decrease blood flow to the optic nerve and lead to sudden unilateral decrease in vision. Because NAION may lead to permanent vision loss, the FDA has required inclusion of warnings on the product labeling of phosphodiesterase inhibitors. Specifically, before receiving these agents, patients at risk...

for NAION should be evaluated by an ophthalmologist. Patients at risk include a wide variety of patients: those with glaucoma, macular degeneration, diabetic retinopathy or hypertension, those who have undergone eye surgery or have experienced eye trauma, patients who are age 50 years or more, or smokers. A patient who experiences sudden vision loss while taking a phosphodiesterase inhibitor should be evaluated for NAION before continuing treatment.40

Tadalafil produces lower back and limb muscle pain, which occur in a dose-related fashion in 7% to 30% of patients treated with doses of 10 to 100 mg.41 The mechanism for this is not known. It may be linked to inhibition of type 11 phosphodiesterase, a unique characteristic of tadalafil.

Vardenafil can cause prolongation of the QT interval. Therefore, it should be used cautiously in patients with this anomaly or in patients who are taking medications that prolong the QT interval (e.g., quinidine).

Priapism is a rare adverse effect of phosphodiesterase inhibitors, particularly sildenafil and vardenafil, which have shorter plasma half-lives than tadalafil. Priapism has been associated with excessive doses of the phosphodiesterase inhibitor or concomitant therapy involving other erekogenic drugs.

Drug Interactions

Patients taking organic nitrates may develop severe hypotension if they are taken with phosphodiesterase inhibitors as a result of two major factors: (1) organic nitrates on their own produce hypotension, and (2) organic nitrates are nitric oxide donors, which can stimulate the activity of guanylate cyclase and increase tissue levels of cGMP. For this reason, use of the three phosphodiesterase inhibitors is contraindicated in patients taking nitrates given by any route at scheduled times or intermittently.19,42 Furthermore, nitrates should be withheld for 24 hours after sildenafil or vardenafil administration and for 48 hours after tadalafil administration.19,42 Finally, if a patient who has taken a phosphodiesterase inhibitor requires medical treatment of angina, non–nitrate-containing agents (e.g., calcium channel blocker, β-adrenergic antagonist, morphine) should be used.

If severe hypotension occurs after exposure to nitrates and a phosphodiesterase inhibitor, the patient should be placed in a Trendelenburg position and aggressive fluid administration initiated. If severe hypotension continues, parenteral β-adrenergic agonists (e.g., dopamine) should be administered cautiously.

Interestingly, dietary sources of nitrates, nitrites, or L-arginine (a precursor for nitrates) do not interact with the phosphodiesterase inhibitors. This is because dietary sources do not increase circulating levels of nitric oxide in humans.

Sildenafil does not appear to interact with antihypertensive medications. In retrospective analyses of patients taking sildenafil in combination with α-adrenergic antagonists, β-adrenergic antagonists, diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or calcium channel blockers, the incidence of hypotension was similar to that reported in patients taking sildenafil alone.43,44 This finding was confirmed by a retrospective analysis of pooled data on more than 4,800 patients in 35 clinical trials.39

Small decreases in blood pressure with clinically symptomatic hypotension have been described in some patients taking sildenafil and tadalafil and immediate-release formulations of terazosin and doxazosin.45 In contrast, concurrent administration of extended-release alfuzosin, silodosin, or tamsulosin, which produce lower peak serum concentrations than immediate-release formulations after administration or exhibit α1-adrenergic selectivity, show minimal or no decrease in blood pressure.46-48 Package labeling for phosphodiesterase inhibitors include a caution about concomitant use of phosphodiesterase inhibitors and α-adrenergic antagonists.

Hepatic metabolism of all three phosphodiesterase inhibitors can be inhibited by enzyme inhibitors of CYP 3A4, including cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, saquinavir, and grapefruit juice.49-51 Lower starting doses should be used in these patients (see Table 92–4).
CHAPTER 92

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels.

**Efficacy**

Testosterone replacement regimens restore muscle strength and sexual drive and improve mood in patients with hypogonadism. Improvements are generally observed within days or weeks of the start of testosterone replacement. Administration of testosterone will correct the serum testosterone level to the normal range. No additional benefit has been demonstrated for large doses of testosterone, which increase the serum testosterone level from the low end to the upper end of the normal range or to the above-normal range.\(^5\) Testosterone replacement regimens do not directly correct erectile dysfunction; instead, they improve libido, thereby correcting secondary erectile dysfunction.\(^4\)

Testosterone replacement regimens can be administered orally, parenterally, or transdermally (Table 92–6). Injectable testosterone replacement regimens are the preferred treatment for symptomatic patients with primary or secondary hypogonadism because they are effective, inexpensive, and not associated with the bioavailability problems or hepatotoxic adverse effects of oral androgens.\(^5\) Although convenient for the patient, testosterone patches and gels are much more expensive than other forms of androgen replacement; therefore, they should be reserved for patients who refuse injectable testosterone.

In the ideal testosterone replacement regimen, the medication would mimic the normal circadian pattern of serum testosterone concentrations such that peak and trough concentrations occur in the early morning and late afternoon, respectively; produce serum concentrations in the normal range; produce serum concentrations of dihydrotestosterone and estradiol, which are metabolites of testosterone that mimic the normal physiologic pattern; and produce minimal adverse effects.\(^5\) Table 92–6 compares commercially available testosterone replacement regimens for these characteristics and shows that an ideal regimen has yet to be identified.

**Mechanism**

Testosterone replacement regimens supply exogenous testosterone and restore serum testosterone levels to the normal range (300–1,100 ng/dL; 10.4–38.2 nmol/L). In so doing, testosterone replacement regimens correct symptoms of hypogonadism, which include malaise, loss of muscle strength, depressed mood, and decreased libido. Testosterone can directly stimulate androgen receptors in the central nervous system and is thought to be responsible for maintaining normal sexual drive. In addition, testosterone may stimulate nitric oxide synthase, thereby increasing cavernosal concentrations of nitric oxide, and enhancing the effects of phosphodiesterase type 5 in cavernosal tissue.\(^5\)

**Indications**

Testosterone replacement regimens are indicated in symptomatic patients with primary or secondary hypogonadism, as confirmed by both the presence of a decreased libido and low serum concentrations of testosterone.\(^18\) Serum testosterone concentrations typically are measured in the early morning because the secretion pattern of this hormone follows a circadian pattern, with highest serum concentrations in the morning hours. Simultaneous serum luteinizing hormone levels help to distinguish patients with primary hypogonadism, who have elevated luteinizing hormone levels, from those with secondary hypogonadism, who have decreased luteinizing hormone levels. Primary hypogonadism can be a characteristic of aging men who undergo andropause, in which the Leydig cells of the testes slowly and progressively decrease testosterone production.\(^12\) Symptoms, including decreased libido, erectile dysfunction, gynecomastia, decreased muscle mass, increased body fat, and osteopenia, develop gradually over years.

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels.

Pharmacokinetics

Natural testosterone has poor oral bioavailability because of extensive first-pass hepatic metabolism; therefore, large doses must be taken. To improve oral bioavailability, alkylated derivatives were formulated. Of these derivatives, methyltestosterone and fluoxymesterone are more resistant to hepatic catabolism and can be taken in smaller daily doses, which are potentially safer. However, oral alkylated derivatives of testosterone are not metabolized to dihydrotestosterone or estradiol, and are associated with a higher incidence of serious hepatotoxicity and therefore are not preferred for management of hypogonadism. An alternative to oral administration is the testosterone buccal system (Striant), which is applied to the gum above the upper incisors twice per day. Over time it forms a gel from which testosterone is absorbed. One advantage of this route of administration is that the drug bypasses first-pass hepatic catabolism, which allows for increased bioavailability of testosterone.

Several testosterone esters have been formulated for intramuscular injection, with different durations of action (see Table 92–3). The shorter-acting testosterone propionate, which requires dosing 3 times per week, has been replaced with testosterone cypionate or enanthate, which can be dosed every 2, 4, or 6 weeks in most patients. An even longer-acting parenteral testosterone is available as a subcutaneous implant for dosing every 3 to 6 months. Although this schedule minimizes repeat visits to the clinician’s office for dosing, the implant must be administered by a physician, and the implanted pellet may be extruded after administration. This extrusion has been reported in up to 8.5% of treated patients and results in loss of drug effect. These testosterone formulations produce supraphysiologic patterns of serum testosterone during the dosing interval, which have been linked to mood swings in some patients.

Topical testosterone replacement regimens can be delivered as once-daily patches or gel. Testosterone patches increase serum testosterone levels into the normal range in 2 to 6 hours. Serum testosterone levels return to baseline 24 hours after patch administration. However, unlike oral or injectable supplements, transdermal testosterone patches applied at bedtime or testosterone gel applied each morning produce physiologic patterns of serum testosterone levels throughout the day. The clinical importance of this biochemical effect is unknown. The original Testoderm brand patch was formulated for scrotal application. Scrotal skin is thinner and has a richer vascular supply than does the skin on the arms or thighs. Therefore, application of Testoderm patches produces excellent absorption of the hormone. However, the patch can fall off when the scrotum becomes damp or moist, when the patient exercises, or if the scrotum is excessively hairy.

For improved convenience, Androderm and Testoderm TTS patches were formulated for application to the arms, buttocks, or back; Androderm can also be applied to the thighs. The addition of absorption enhancers and different adhesives has been linked to a higher incidence of contact dermatitis with Androderm patches compared with the original Testoderm scrotal patch. Testosterone gel 1% formulation (AndroGel) is applied in much larger doses (5 or 10 g each day) to the skin of the shoulders, upper arms, or abdomen. The hormone is absorbed quickly, within 30 minutes, but several hours may be required for complete absorption of the dose. For this reason, the patient should be reminded to wait at least 5 to 6 hours after application before showering. To prevent inadvertent transfer of testosterone gel to others, the patient should thoroughly wash his hands with soap and water after administration of a dose, and allow the application site to dry undisturbed for several minutes before dressing or covering it.

Dosing

Table 92–3 lists the usual doses for testosterone replacement regimens. Two to 3 months is considered an adequate treatment trial with a particular dose. Thus, a dose should not be increased until the patient has used one particular dose for at least this time period. The serum testosterone level should return to the normal range and symptoms of androgen deficiency should be relieved with appropriate dosing.

Before initiating any testosterone replacement regimen in patients 40 years and older, patients should be screened for benign prostatic hyperplasia and prostate cancer. Both of these diseases are testosterone-dependent conditions and theoretically could be worsened by exogenous administration of testosterone. Prostate cancer is a contraindication to androgen supplementation. To screen for these conditions, a prostate-specific antigen serum concentration should be obtained and a digital rectal examination of the prostate performed. These tests are generally repeated at 1-year intervals after treatment is started.

Adverse Effects

Testosterone replacement regimens can cause sodium retention, which can cause weight gain, or exacerbate hypertension, congestive heart failure, and edema. Gynecomastia can occur as a result of conversion of testosterone to estrogen in peripheral tissues. This has been reported most often in patients with liver cirrhosis.

Testosterone replacement regimens are contraindicated in patients with breast cancer and untreated prostate cancer. Although serum lipoprotein perturbations may occur, testosterone replacement regimens have a neutral effect in that they decrease both total cholesterol and high-density lipoprotein cholesterol levels. No cases of cardiovascular disease have been reported with testosterone replacement regimens.

Large doses of parenteral testosterone can produce adverse metabolic effects. Thus, patients on long-term testosterone replacement regimens must undergo clinical laboratory testing for a serum testosterone level and hematocrit before starting treatment and every 6 to 12 months during treatment. Repeated serum testosterone levels that exceed the normal range require a dosage reduction or increased interval between drug doses. If the hematocrit exceeds 55% (0.55), the testosterone replacement regimen should be withheld to avoid polycythemia and its consequences.

Oral alkylated testosterone replacement regimens have caused hepatotoxicity, ranging from mild elevations of hepatic transaminases to serious liver diseases, including peliosis hepatis (hemorrhagic liver cysts), hepatocellular and intrahepatic cholestasis, and benign or malignant tumors. For this reason, parenteral testosterone replacement regimens are preferred.

Topical testosterone patches may cause contact dermatitis, which responds well to topical corticosteroids. This adverse effect has been associated with the presence of permeation enhancers, which are added to patch formulations. If the dermatitis becomes problematic, an alternative is testosterone gel formulations, which are associated with a lower incidence of contact dermatitis compared with patches.

■ ALPROSTADIL

Mechanism

Alprostadil, also known as prostaglandin E1, stimulates adenyl cyclase, resulting in increased production of cAMP, a secondary messenger that decreases the intracellular calcium concentration and causes smooth muscle relaxation of the arterial blood vessels and sinusoidal tissues in the corpora. This results in enhanced blood flow to and blood filling of the corpora.

Alprostadil is commercially available as an intracavernosal injection (Caverject and Edex) and as an intrarethral insert (medicated urethral system for erection [MUSE]).
Indications
Both commercially available formulations of alprostadil are FDA approved as monotherapy for management of erectile dysfunction. Alprostadil is more effective by the intracavernosal route than the intraurethral route.

The enhanced efficacy of the intracavernosal injection may be related to the excellent bioavailability of the drug when injected directly into the corpora cavernosa. In contrast, intraurethral alprostadil doses generally are several hundred times larger than intracavernosal doses. This is because intraurethral alprostadil must be absorbed from the urethra, through the corpus spongiosum, and into the corpus cavernosum, where it exerts its full proerectogenic effect.

Although several other agents, including papaverine, phen tolamine, and atropine, have been used off-label for intracavernosal therapy, alprostadil is preferentially prescribed. This is because intracavernosal alprostadil has been FDA approved for erectile dysfunction; it does not require extemporaneous compounding, and it has a low potential for causing prolonged erections and priapism.

Both formulations of alprostadil are considered more invasive than VEDs or phosphodiesterase inhibitors. For this reason, intracavernosal alprostadil is generally prescribed after patients do not respond to or cannot use less invasive interventions. Intracavernosal alprostadil is preferred over intraurethral alprostadil because of its greater effectiveness. Intracavernosal alprostadil may be preferred in patients with diabetes mellitus, who are accustomed to injectable drug therapy and may have peripheral neuropathies, which decrease the patient’s perception of pain upon injection. Intraurethral alprostadil is generally reserved as a treatment of last resort for patients who do not respond to other less invasive and more effective forms of therapy and who refuse surgery.

Intracavernosal Alprostadil
Efficacy The overall efficacy of intracavernosal alprostadil is 70% to 90%. Three characteristics of intracavernosal alprostadil include the following:

1. The effectiveness of alprostadil is dose related over the range of 2.5 to 20 mcg. The mean duration of erection is directly related to the dose of alprostadil administered and ranges from 12 to 44 minutes.

2. A higher percentage of patients with psychogenic and neurogenic erectile dysfunction respond to alprostadil at a lower dose compared to patients with vasculogenic erectile dysfunction.

3. Tolerance does not appear to develop with continued use of intracavernosal alprostadil at home.

Although 70% to 75% of patients respond to intracavernosal alprostadil, a high proportion of patients elect to discontinue its use over time. Depending on the study and the length of observation, 30% to 50% of patients voluntarily discontinue therapy, usually during the first 6 to 12 months. Common reasons for discontinuation include lack of perceived effectiveness; inconvenience of administration; an unnatural, nonspontaneous erection; needle phobia; loss of interest; and cost of therapy.

Approximately one third of patients do not respond to usual doses of intracavernosal alprostadil. In these patients, intracavernosal alprostadil has been used successfully along with VEDs. Such combination therapy can be attempted by patients before transitioning to more invasive surgical procedures. Alternatively, intracavernosal injections of synergistic combinations of vasoactive agents that act by different mechanisms have been used. Intracavernosal drug combinations typically produce an erection that lasts longer than an erection produced by any one of the agents in the mixture. In addition, because of the low dosage of each agent in the combination, fewer systemic and local fibrotic adverse effects develop compared with high-dose monotherapy. For example, when used in low-dose combination regimens, papaverine is less likely to induce hypotension and liver dysfunction, and phenolamine is less likely to induce tachycardia and hypotension. However, as previously mentioned, such intracavernosal drug combinations are not commercially available and must be extemporaneously compounded.

Pharmacokinetics Intracavernosal injection should be administered into only one corpus cavernosum. From this injection site, the drug will reach the other corpus cavernosum through vascular communications between the two corpora. Alprostadil acts rapidly, with an onset of 5 to 15 minutes. The duration is directly related to the dose. Within the usual dosage range of 2.5 to 20 mcg, the duration of erection is no more than 1 hour. Higher doses are expected to exhibit a longer duration of action. Local enzymes in the corpora cavernosum quickly metabolize alprostadil. Any alprostadil that escapes into the systemic circulation is deactivated on first pass through the lungs. Hence, the plasma half-life of alprostadil is approximately 1 minute, and the potential for systemic adverse effects is negligible. Dose modification is not necessary in patients with renal or hepatic disease.

Dosing The usual dose of intracavernosal alprostadil is 10 to 20 mcg, with a maximum recommended dose of 60 mcg. Doses greater than 60 mcg have not produced any greater improvement in penile erection but may cause hypotension or prolonged erections lasting more than 1 hour. The dose should be administered 5 to 10 minutes before intercourse. The manufacturer recommends that patients be slowly titrated up to the minimally effective dosage to minimize the likelihood of hypotension. Under a physician’s supervision, patients should start with a 1.25-mcg dose, which can be increased in increments of 1.25 to 2.50 mcg at 30-minute intervals up to the lowest dose that produces a firm erection for 1 hour and does not produce adverse effects. In clinical practice, this process is rarely done because it is time consuming. Thus, many physicians start the patient on 10 mcg and move quickly up the dosage range to identify the best dose for the patient. To avoid adverse effects, patients should receive no more than one injection per day and not more than three injections per week.

Intracavernosal injections should be performed using a 0.5-inch, 27- or 30-gauge needle. A tuberculin syringe or a syringe prefilled with diluent as supplied by the manufacturer should be used to ensure precise measurement of doses. Patients with needle phobia, poor vision, or poor manual dexterity can use commercially available autoinjectors (e.g., PenInj ect) to facilitate administration of intracavernosal alprostadil.

Intracavernosal injections require that the patient or the sexual partner practice good aseptic technique (to avoid infection), have good manual skills and visual ability, and be comfortable with injection techniques. When practicing self-injection, the patient should use one hand to firmly hold the glans penis against his thigh to expose the lateral surface of the shaft. The injection should be made at right angles into one of the lateral surfaces of the proximal third of the penis. The injection should never be made into the dorsal or ventral surface of the penis. This will prevent inadvertent injection of the drug into arteries on the dorsal surface or the urethra on the ventral surface. After the injection, the penis should be massaged to help distribute the drug into the opposite corpus cavernosum. Injection sites should be rotated with each dose. Finally, manual pressure should be applied to the injection site for 5 minutes to reduce the likelihood of hematoma formation (Fig. 92-5).

Once the optimal dosage of intracavernosal alprostadil is established, the patient should return for routine medical follow-up every 3 to 6 months. Some patients subsequently require dosage adjustment, largely attributed to worsening of the underlying disease that is contributing to the erectile dysfunction.
Priapism, a prolonged, painful erection lasting more than 1 hour, occurs in 1% to 15% of treated patients. It occurs most often during the dose titration period and is rare thereafter. Blood sludging in the corpora can lead to tissue hypoxia and cavernosal fibrosis and scarring. The risk for this complication is greatest for erections that persist beyond 4 hours. Patients are advised to seek medical attention immediately when drug-induced erections last more than 1 hour, as this is considered a urologic emergency. Its management includes supportive care, including analgesics for pain and sedatives for anxiety. In addition, needle aspiration of sludged blood in the corpora or intracavernosal injection of α-adrenergic agonists (e.g., phenylephrine) has been used. These procedures facilitate venous drainage of the corpora, allowing venous outflow to “catch up” with arterial inflow.

The likelihood of prolonged erections with intracavernosal alprostadil is dose related. Therefore, to prevent this adverse effect, the lowest effective dose should be used, and the dose should be titrated to ensure that the duration of the erection is no more than 1 hour.

Other local adverse effects include injection site hematomas and bruising. These effects are largely the result of poor injection technique. To minimize the risk of injection site hematomas, patients should be advised to apply pressure to the injection site for 5 minutes after each dose. Similarly, infection at the injection site has been reported. Meticulous aseptic technique is necessary to prevent this complication.

Intracavernosal alprostadil rarely causes systemic adverse effects, owing to the agent’s local catabolism in cavernosal tissue and rapid deactivation in pulmonary tissue (if any of the drug escapes into the systemic circulation). However, large doses greater than 20 mcg are associated with dizziness and hypotension in some patients and is one reason why such large doses are not commonly used.

Intracavernosal injection therapy should be used cautiously by patients at risk for priapism, including patients with sickle cell disease or lymphoproliferative disorders. It should be used cautiously by patients who may develop bleeding complications secondary to injections, including patients with thrombocytopenia or those taking anticoagulants. It also should be used cautiously by patients who use poor-quality injection technique, including patients with psychiatric disorders, obese patients (who may not be able to reach or see the penile injection site), patients who are blind, and patients with severe arthritis.

**Intraurethral Alprostadil**

**Efficacy** Intraurethral alprostadil inserts are marketed as MUSE, which contains a medication pellet inside a prefilled urethral applicator. Multiple studies show this product has an overall effectiveness rate of 43% to 65% compared with 70% to 90% for intracavernosal alprostadil. Its decreased effectiveness and inconvenient administration method have resulted in this product being considered a third-line treatment option for patients with erectile dysfunction. However, some patients respond to intraurethral alprostadil even though they did not respond to intracavernosal alprostadil.

Intraurethral alprostadil has been combined with an adjustable penile constriction band to improve treatment response.

**Pharmacokinetics** Following intraurethral instillation, alprostadil is absorbed quickly through the urethra, into the corpus spongiosum, and then into the corpora cavernosa. As much as 90% of each dose is absorbed by the urethra and corpus spongiosum in less than 10 minutes, with peak absorption occurring in 20 to 25 minutes. An estimated 20% of each dose is delivered to the corpora cavernosa. As with intracavernosal injections of alprostadil, any drug absorbed into the systemic circulation is rapidly metabolized on first pass through the lungs.
Erectile Dysfunction

CHAPTER 92

Yohimbine

Yohimbine, a tree-bark derivative also known as yohimbe, is widely used as an aphrodisiac. Yohimbine is a central α₂-adrenergic antagonistic that increases catecholamines and improves mood. Some investigators believe that yohimbine has peripheral proerectogenic effects. Yohimbine may reduce peripheral α₁-adrenergic tone, thereby permitting a predominant cholinergic tone, which could result in a vasodilatory response. ⁵, ⁶⁴ The usual oral dose is 5.4 mg 3 times per day.

A controlled clinical trial has shown that high-dose yohimbine (100 mg daily) is no more effective than placebo. ⁶⁵ Based on a meta-analysis of published studies that came to the same conclusion, the American Urological Association has cautioned against the use of yohimbine. ²⁴ In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension.

The onset after intraurethral insertion is similar to that of intracavernosal injection, 5 to 10 minutes.

**Dosing** The usual dose of intraurethral alprostadil is 125 to 1,000 mcg. The dose should be administered 5 to 10 minutes before sexual intercourse. No more than two doses per day are recommended. Before administration, the patient should be advised to empty his bladder, voiding completely.

Similar to intracavernosal injection treatments, intraurethral insertion of alprostadil requires good manual and visual skills to minimize the risk of urethral injuries. Intraurethral alprostadil is supplied in a prefilled intraurethral applicator. The patient should void first. With one hand the patient holds the glans penis, and with the other hand the patient inserts the intraurethral applicator 0.5 inch (1.3 cm) into the urethra. The drug pellet is then pushed into the urethra. The penis should be massaged to enhance drug dissolution in the urethral fluids and drug absorption (Fig. 92–6).

**Adverse Effects** The urethra can be injured because of improper administration technique. Injuries can lead to urethral stricture and difficulty voiding. Patients should receive complete education about optimal administration procedures before starting treatment.

Urethral pain has been reported in 24% to 32% of patients. Usually it is mild and does not require discontinuation of treatment. Female sexual partners may experience vaginal burning, itching, or pain, which probably is related to transfer of alprostadil from the man’s urethra to the woman’s vagina during intercourse.

Prolonged painful erections (priapism) have been rarely reported. Syncope and dizziness have been reported rarely (only 2%–3% of patients) and likely are related to use of excessively large doses.

---

**UNAPPROVED AGENTS**

A variety of other commercially available and investigational agents have been used for management of erectile dysfunction. Although it is beyond the scope of this chapter to discuss all of them, some of the more commonly used agents are discussed here.

**Trazodone**

The mechanism by which trazodone produces an erection is not clear. It likely acts peripherally to antagonize α₁-adrenergic receptors. As a result, a predominant cholinergic effect results, which causes peripheral arteriolar vasodilation and relaxation of cavernosal tissues, enhancing blood filling of the corpora. Intracavernosal injection of trazodone in experimental studies supports this likely mechanism. ⁶²

Although some clinical trials suggested that trazodone 50 to 200 mg daily by mouth might be effective in the management of erectile dysfunction, these trials were generally poorly controlled, were nonrandomized, included small samples treated for short time periods, and did not include validated objective parameters of response. ⁵, ⁶³

The adverse effects of trazodone, when used for erectile dysfunction, are similar to those reported with trazodone when used to treat depression and include dry mouth, sedation, and dizziness.

**Yohimbine**

Yohimbine, a tree-bark derivative also known as yohimbe, is widely used as an aphrodisiac. Yohimbine is a central α₂-adrenergic antagonistic that increases catecholamines and improves mood. Some investigators believe that yohimbine has peripheral proerectogenic effects. Yohimbine may reduce peripheral α₁-adrenergic tone, thereby permitting a predominant cholinergic tone, which could result in a vasodilatory response. ⁵, ⁶⁴ The usual oral dose is 5.4 mg 3 times per day.

A controlled clinical trial has shown that high-dose yohimbine (100 mg daily) is no more effective than placebo. ⁶⁵ Based on a meta-analysis of published studies that came to the same conclusion, the American Urological Association has cautioned against the use of yohimbine. ²⁴ In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension.
Papaverine

Papaverine is a nonspecific phosphodiesterase inhibitor that decreases metabolic catabolism of cAMP in cavernosal tissue. As a result of enhanced tissue levels of cAMP, smooth muscle relaxation occurs. Cavernosal sinusoids fill with blood, and a penile erection results.

Papaverine is not FDA approved for erectile dysfunction. Intracavernosal papaverine alone is not commonly used for management of erectile dysfunction because the large doses required produce dose-related adverse effects, such as priapism, corporal fibrosis, hypotension, and hepatotoxicity.\(^5\) Papaverine is more often administered in lower doses combined with phentolamine and/or alprostadil. A variety of formulas have been used, but no one mixture has been proven better than other mixtures (see Table 92–6). Combination formulations are considered safer and are associated with the potential for fewer serious adverse effects than high doses of any one of these agents.

A portion of each papaverine dose is systemically absorbed, and its prolonged plasma half-life of 1 hour contributes to adverse effects. The usual dose of papaverine is 7.5 to 60 mg when used as a single agent for intracavernosal injection. When used in combination, the dose decreases to 0.5 to 20 mg.

If treated with papaverine, patients with a history of underlying liver disease or alcohol abuse should undergo liver function testing at baseline and every 6 to 12 months during continued treatment.

Phentolamine

Phentolamine is a competitive nonselective \(\alpha\)-adrenergic blocking agent. It reduces peripheral adrenergic tone and enhances cholinergic tone. As a result, it improves cavernosal filling and is proerectogenic.

Phentolamine has most often been administered as an intracavernosal injection. Monotherapy is avoided because large doses are required for an erection, and at these large doses systemic hypotensive adverse effects would be prevalent. Most often, phentolamine has been used in combination with other vasoactive agents for intracavernosal administration. A ratio of 30 mg papaverine to 0.5 to 1 mg phentolamine is typical, and the usual dose ranges from 0.1 to 1 mL of the mixture. Such a mixture promotes local effects of phentolamine and minimizes systemic hypotensive adverse effects.

Hypotension is the most common adverse effect of intracavernosal phentolamine. It is more common and more severe with large doses or in patients with poor injection technique who have injected into a vein (rather than the cavernosa). Prolonged erections have been reported in patients who used excessive doses of intracavernosal medications in combination.

### EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcomes of specific treatments for erectile dysfunction include (1) improvement in the quantity and quality of penile erections suitable for intercourse and (2) avoidance of adverse drug reactions and drug interactions.

At baseline and after the patient has completed a clinical trial period of 1 to 3 weeks with a specific treatment for erectile dysfunction, the physician should conduct assessments to determine whether the quality and quantity of penile erections has improved. A patient’s level of satisfaction is highly individualized, depending on his lifestyle and expectations. Therefore, a patient who has successful intercourse once per week might be completely satisfied, whereas another patient might judge this to be unsatisfactory. Patients with unrealistic expectations in this regard must be identified and counseled by clinicians to avoid adverse effects of excessive use of erectogenic agents.

Failure to improve the quality and quantity of penile erections suitable for intercourse after an appropriate clinical trial period with a specific treatment for erectile dysfunction occurs in a devices with fewer mechanical parts. These devices can be placed during shorter surgical procedures and have a low 5-year mechanical failure rate (6%–10%) as compared with the original inflatable prostheses (Fig. 92–7).\(^6\)

Penile prostheses provide penile rigidity suitable for vaginal intercourse and are associated with a greater than 90% patient satisfaction rate, which is generally higher than that observed with any other drug treatment or VED.\(^4\) The surgical success rate after insertion is 82% to 98%.\(^5\)

Adverse effects of prosthesis insertion can occur early or late after the surgical procedure. The most common early complication is infection. Late complications include mechanical failure of the prosthesis, particularly when an inflatable prosthesis has been inserted. With improved technology, the mechanical failure rate has decreased to 5%.\(^5\) Other late complications include erosion of the rods through the penis or late-onset infection. Although some salvage procedures have been devised, in many cases the prosthesis requires removal.

### PENILE PROSTHESSES

Surgical insertion of a penile prosthesis is the most invasive treatment of erectile dysfunction. It is reserved for patients who do not respond to or who are not candidates for less invasive oral or injectable treatments.

Prosthesis insertion requires anesthesia and skilled urologists. Two prostheses are widely used: malleable and inflatable. Malleable or semirigid prostheses consist of two bendable rods that are inserted into the corpora cavernosa. The patient appears to have a permanent erection after the procedure; the patient is able to bend the penis into position at the time of intercourse.

The inflatable prosthesis has several mechanical parts. The inflatable prosthesis produces a more natural erection. The patient develops an erection only when the device is activated. Some newer advances in inflatable prosthesis technology have resulted in
significant percentage of patients. In this case, physicians generally take the following steps in order:

1. Ensure that the patient has been prescribed a maximum tolerated dose and has an adequate clinical trial of a specific treatment before discarding it as ineffective.

2. Switch to another drug (see Fig. 92–4).

CONCLUSIONS

Erectile dysfunction is a common disorder of aging men. Its incidence is higher in patients with underlying medical disorders that compromise the vascular, neurologic, hormonal, or psychogenic systems necessary for a normal penile erection. Medications are common causes of erectile dysfunction. By correcting the underlying etiology, erectile dysfunction can often be reversed without the use of specific treatments.

When treatments of erectile dysfunction are needed, the least invasive forms of treatment should be used first because they produce the lowest incidence of serious adverse effects. VEDs or phosphodiesterase inhibitors are considered first-line treatments. If these treatments fail, intracavernosal alprostadil injection therapy can be initiated. If this treatment fails, the patient can attempt a combination of intracavernosal alprostadil plus VED, combination intracavernosal therapy, or intraurethral alprostadil. If this treatment fails, the patient may require insertion of a penile prosthesis.

Some insurance companies do not reimburse for drug treatments for erectile dysfunction, so cost is an important issue for some patients.

Clinicians should provide clear and simple advice. Patient confidentiality and privacy, which are extremely important to men with erectile dysfunction, should be maintained at all times.

ABBREVIATIONS

cAMP: cyclic adenosine monophosphate
cGMP: cyclic guanosine monophosphate
VED: vacuum erection device

KEY CONCEPTS

1. Although symptomatic benign prostatic hyperplasia (BPH) is rare in men younger than 50 years of age, it is very common in men 60 years and older because of androgen-driven growth in the size of the prostate. Symptoms commonly result from both static and dynamic factors.

2. BPH symptoms may be exacerbated by medications, including antihistamines, phenothiazines, tricyclic antidepressants, and anticholinergic agents. In these cases, discontinuing the causative agent can relieve symptoms.

3. Specific treatments for BPH include watchful waiting, drug therapy, and surgery.

4. For patients with mild disease who are asymptomatic or have mildly bothersome symptoms and no complications of BPH disease, no specific treatment is indicated. These patients can be managed with watchful waiting. Watchful waiting includes behavior modification and return visits to the physician at 12-month intervals for assessment of worsening symptoms or signs of BPH.

5. If symptoms progress to a moderate or severe level, drug therapy or surgery is indicated. Drug therapy with an \( \alpha_1 \)-adrenergic antagonist is an interim measure that relieves voiding symptoms. In select patients with prostates of at least 40 g, 5\( \alpha \)-reductase inhibitors delay symptom progression and reduce the incidence of BPH-related complications.

6. All \( \alpha_1 \)-adrenergic antagonists are equally effective in relieving BPH symptoms. Older second-generation immediate-release formulations of \( \alpha_1 \)-adrenergic antagonists (e.g., terazosin, doxazosin) can cause adverse cardiovascular effects, mainly first-dose syncope, orthostatic hypotension, and dizziness. For patients who can not tolerate hypotensive effects of the second-generation agents, the third-generation, pharmacologically uroselective agents (e.g., tamsulosin, silodosin) are good alternatives. An extended-release formulation of alfuzosin, a second-generation, functionally uroselective agent, has fewer cardiovascular adverse effects than immediate-release formulations of terazosin or doxazosin; however, whether extended-release doxazosin, alfuzosin, or silodosin have the same cardiovascular safety profile as tamsulosin is unclear.

7. 5\( \alpha \)-Reductase inhibitors are useful primarily for patients with large prostates greater than 40 g who wish to avoid surgery, and can not tolerate the side effects of \( \alpha_1 \)-adrenergic antagonists. 5\( \alpha \)-Reductase inhibitors have a slow onset of action, taking up to 6 months to exert maximal clinical effects, which is a disadvantage of their use. In addition, decreased libido, erectile dysfunction, and ejaculation disorders are common adverse effects, which may be troublesome problems in sexually active patients.

8. Surgery is indicated for moderate to severe symptoms of BPH for patients who do not respond to or do not tolerate drug therapy or for patients with complications of BPH. It is the most effective mode of treatment in that it relieves symptoms in the greatest number of men with BPH. However, the two most widely used techniques, transurethral resection of the prostate and open prostatectomy, are associated with the highest rates of complications, including retrograde ejaculation and erectile dysfunction. Therefore, minimally invasive surgical procedures are often desired by patients. These relieve symptoms and are associated with a lower rate of adverse effects, but they have a higher reoperation rate than the gold standard procedures.

9. Although widely used in Europe for treatment of BPH, phytotherapy should be avoided. Studies of these herbal medicines are inconclusive, and the purity of available products is questionable.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.
but some urinary voiding symptoms are present by the time men turn 60 years of age. The Boston Area Normative Aging Study estimated that the cumulative incidence of clinical BPH was 78% for patients at age 80 years. Similarly, the Baltimore Longitudinal Study of Aging projected that approximately 60% of men at least 60 years old develop clinical BPH.

### NORMAL PROSTATE PHYSIOLOGY

Located anterior to the rectum, the prostate is a small heart-shaped, chestnut-sized gland located below the urinary bladder. It surrounds the proximal urethra like a doughnut.

Soft, symmetric, and mobile on palpation, a normal prostate gland in an adult man weighs 15 to 20 g. Physical examination of the prostate must be done by digital rectal examination (i.e., the prostate is manually palpated by inserting a finger into the rectum). Thus, the prostate is examined through the rectal mucosa.

The prostate has two major functions: (1) to secrete fluids that make up a portion (20%–40%) of the ejaculate volume and (2) to provide secretions with antibacterial effect possibly related to its high concentration of zinc.

At birth, the prostate is the size of a pea and weighs approximately 1 g. The prostate remains that size until the boy reaches puberty. At that time, the prostate undergoes its first growth spurt, growing to its normal adult size of 15 to 20 g by the time the young man is 25 to 30 years of age. The prostate remains this size until the patient reaches age 40 years, when a second growth spurt begins and continues for the rest of his lifetime. During this period, the prostate can quadruple in size or grow even larger.

The prostate gland comprises three types of tissue: epithelial tissue, stromal tissue, and the capsule. Epithelial tissue, also known as glandular tissue, produces prostatic secretions. These secretions are delivered into the urethra during ejaculation and contribute to the total ejaculate volume. Androgens stimulate epithelial tissue growth. Stromal tissue, also known as smooth muscle tissue, is embedded with $\alpha_1$-adrenergic receptors. Stimulation of these receptors by norepinephrine causes smooth muscle contraction, which results in an extrinsic compression of the urethra, reduction of the urethral lumen, and decreased urinary bladder emptying. The normal prostate is composed of a higher amount of stromal tissue than epithelial tissue, as reflected by a stromal-to-epithelial tissue ratio of 2:1. This ratio is exaggerated to 5:1 for patients with BPH, which explains why $\alpha_1$-adrenergic antagonists are quickly effective in symptomatic management and why 5α-reductase inhibitors reduce an enlarged prostate gland by only 25%.

The capsule, or outer shell of the prostate, is composed of fibrous connective tissue and smooth muscle, which also is embedded with $\alpha_1$-adrenergic receptors. When stimulated with norepinephrine, the capsule contracts around the urethra (Fig. 93-1).

Testosterone is the principal testicular androgen in males, whereas androstenedione is the principal adrenal androgen. These two hormones are responsible for penile and scrotal enlargement, increased muscle mass, and maintenance of the normal male libido. These androgens are converted by 5α-reductase in target cells to dihydrotestosterone (DHT), an active metabolite. Two types of 5α-reductase exist. Type I enzyme is localized to sebaceous glands in the frontal scalp, liver, and skin. DHT produced at these target tissues causes acne and increased body and facial hair. Type II enzyme is localized to the prostate, genital tissue, and hair follicles of the scalp. In the prostate, DHT induces growth and enlargement of the gland.

In prostatic cells, DHT has greater affinity for intraprostatic androgen receptors than testosterone, and DHT forms a more stable complex with the androgen receptor. Thus, DHT is considered a more potent androgen than testosterone in the prostate. Of note, despite the decrease in testicular androgen production in the aging male, intracellular DHT levels in the prostate remain normal, probably due to increased activity of intraprostatic 5α-reductase.

Estrogen, a product of peripheral metabolism of androgens, is believed to stimulate the growth of the stromal portion of the prostate gland. Estrogens are produced when testosterone and androstenedione are converted by aromatase enzymes in peripheral adipose tissues. In addition, estrogens may induce the androgen receptor. As men age, the ratio of serum levels of testosterone to estrogen decreases as a result of a decline in testosterone production by the testes and increased adipose tissue conversion of androgen to estrogen.

### PATHOPHYSIOLOGY

Although the precise pathophysiologic mechanisms causing BPH remain unclear, the role of intraprostatic DHT and type II 5α-reductase in the development of BPH is evidenced by several observations:

- BPH does not develop in men who are castrated before puberty.
- Patients with type II 5α-reductase enzyme deficiency do not develop BPH.
- Castration causes an enlarged prostate to shrink.
Patients with BPH can present with a variety of symptoms and signs of disease. All symptoms of BPH can be divided into two categories: obstructive and irritative.

Obstructive symptoms, also known as prostatism or bladder outlet obstruction, result when dynamic and/or static factors reduce bladder emptying. The force of the urinary stream becomes diminished, urinary flow rate decreases, and bladder emptying is incomplete and slow. Patients report urinary hesitancy and straining and a weak urine stream. Urine dribbles out of the penis, and the urinary bladder always feels full, even after patients have voided. Some patients state that they need to press on their bladder to force out the urine. In severe cases, patients may go into urinary retention when bladder emptying is not possible. In these cases, suprapubic pain can result from bladder overdistention.

Approximately 50% to 80% of patients have irritative voiding symptoms, which typically occur late in the disease course. Irritative voiding symptoms result from long-standing, untreated bladder outlet obstruction, and the hyper trophy of bladder muscle is no longer able to generate adequate contractile force to empty the urine past the anatomic obstruction at the bladder neck. Although initially helpful, decompensation eventually occurs, and the hypertrophied bladder muscle is no longer able to generate adequate contractile force as it becomes hypersensitive and ineffective in storing urine. As a result, small amounts of urine irritate the bladder and initiate a bladder emptying response. Patients complain of urinary frequency and urgency. Bedwetting or clothes wetting occurs. Patients report waking up every 1 to 2 hours at night to void (nocturia), which significantly reduces quality of life.

Symptoms of BPH vary over time. Symptoms may improve, remain stable, or worsen spontaneously. Thus, BPH is not necessarily a progressive disease; in fact, some patients experience symptom regression. Between one and two thirds of men with mild disease stabilize or improve without treatment over 2.5 to 5 years. However, other patients experience a slow progression of disease.

Collectively, obstructive and irritative voiding symptoms and their impact on a patient’s quality of life are referred to as lower urinary tract symptoms (LUTS). However, LUTS is not pathognomonic for BPH and may be caused by other diseases, such as neurogenic bladder and urinary tract infection.

Another presentation of BPH is silent prostatism. Patients have obstructive or irritative voiding symptoms but adapt to them and do not voluntarily complain about them. Such patients do not present for medical treatment until complications of BPH disease arise or a spouse brings in a symptomatic patient for medical care.
BPH can be a progressive disease, although the rate of progression is variable among patients.\(^2\) When BPH progresses, it can produce complications that include the following:

- Acute, painful urinary retention, which can lead to acute renal failure
- Persistent gross hematuria when tissue growth exceeds its blood supply
- Overflow urinary incontinence or unstable bladder
- Recurrent urinary tract infection that results from urinary stasis
- Bladder diverticula
- Bladder stones
- Chronic renal failure from long-standing bladder outlet obstruction

Approximately 17% to 20% of patients with symptomatic BPH require treatment because of disease complications.\(^3\) Older men with large prostates greater than 40 g are three times more likely to have severe symptoms or suffer from acute urinary retention and to require prostatectomy than patients with smaller prostates.\(^4\) Thus, a serum PSA level of 1.4 ng/mL (1.4 mcg/L) has been used as a surrogate marker for an enlarged prostate gland to identify patients at risk for developing complications of BPH disease\(^5\) and has been used to guide selection of the most appropriate treatment modality in some patients.\(^6\)\(^7\)

### Diagnostic Evaluation

Because the obstructive and irritative voiding symptoms associated with BPH are not unique to the disease and can be presenting symptoms of other genitourinary tract disorders, including prostate or bladder cancer, neurogenic bladder, prostatic calculi, or urinary tract infection, the patient presenting with signs and symptoms of BPH must be thoroughly evaluated.

A careful medical history should be taken to ensure that a complete listing of symptoms is collected as well as to identify concomitant disorders that may be contributing to voiding symptoms. The medical history should be followed by a thorough medication history, including all prescription and nonprescription medications and dietary supplements that the patient is taking. Any drugs that could be causing or exacerbating the patient’s symptoms should be identified. If possible, the suspected drugs should be discontinued or the dosing regimen modified to ameliorate the voiding symptoms.

The patient should undergo a physical examination, including a digital rectal examination, although the size of the prostate gland may not correspond to symptoms. BPH usually presents as an enlarged, soft, smooth, symmetric gland, greater than 20 g in size. Some patients have only a slightly enlarged gland and yet have bothersome or even serious voiding difficulties. Other patients have an intravesical enlargement of the prostate gland (i.e., the gland grows into the urinary bladder and produces a ball-valve blockage of the bladder neck). This type of prostate enlargement is not palpable on manual examination.

The patient’s perception of the severity of BPH symptoms guides selection of a particular treatment modality in a patient. To evaluate the patient’s perceptions objectively, validated instruments, such as the AUA Symptom Score, are commonly used. Using the AUA index, the patient rates the “bothersomeness” of seven obstructive and irritative voiding symptoms.\(^8\)\(^9\) Each item is rated for severity on a scale from 0 to 5, such that 35 is the maximum score and is consistent with the most severe symptoms. In addition, the patient can complete a voiding diary in which he records the number of voids, the volume of each void, and voiding symptoms for several days. This information is used to evaluate symptom severity and to tailor recommendations for lifestyle modifications that may ameliorate symptoms.

The only clinical laboratory test that must be performed is a urinalysis. Because many of the voiding symptoms of BPH could be caused by other urologic disorders, a urinalysis can help screen for bladder cancer, stones, and infection. To screen for prostate cancer, another common cause of glandular enlargement, a PSA test should be performed for patients aged 40 years or more, with at least a 10-year life expectancy in whom the cost of the test will be outweighed by the potential benefit of diagnosing the disorder.\(^10\)

Additional objective measures of bladder emptying should be performed if surgical treatment is being considered. Measures include peak and average urinary flow rate (normal is at least 10 mL/s). These measures are determined using a uroflowmeter, which checks the rate of urine flow out of the bladder. This is a quick noninvasive outpatient procedure in which the patient is instructed to drink water until his bladder feels full and then the patient’s urinary flow is clocked during voiding. A low urinary flow rate (<10 to 12 mL/s) implies failure of bladder emptying or a functional disorder of the detrusor muscle. Thus, the degree of bladder outlet obstruction correlates poorly with peak urinary flow rate.\(^11\)

Another objective measure is PVR urine volume (normal is 0 mL), which is assessed using a transabdominal ultrasound. A high PVR urine volume (>25 to 30 mL) implies failure of bladder emptying and a predisposition for urinary tract infections. Because of a weak correlation among voiding symptoms, prostate size, and urinary flow rate, most physicians use a combination of measures, including the patient’s assessment of symptoms along with objective evaluation of urinary outflow and presence of complications of BPH to determine the need for treatment.

Many other tests can be performed if additional information is needed to assess the severity of BPH disease and its complications, to assist in the preoperative assessment of the patient, or to distinguish prostate enlargement due to BPH from that caused by prostate cancer. Tests include a serum BUN and creatinine, voiding cystometrogram, transrectal ultrasound of the prostate, intravenous pyelogram, renal ultrasound, and prostate biopsy.

### Treatment

**Benign Prostatic Hyperplasia**

As a disease of symptoms, BPH is treated by relieving bothersome symptoms. Patients usually are stratified into three groups based on disease severity for the purposes of deciding a treatment approach (Table 93–1). However, literature about the natural history of BPH

and the significant risk of disease complications suggests that physicians also should consider preventing serious complications of BPH and decreasing the need for surgery as goals of treatment for select patients. This is a controversial topic complicated by many issues, including the variable costs of treatment options, the inability to clearly distinguish patients who experience spontaneous regression or disease stabilization from those in whom symptoms progress, and the potential benefit that may occur in a comparatively small number of treated patients.

The AUA Guidelines on Management of Benign Prostatic Hyperplasia is the principal tool used in the United States, and the AUA recommendations are similar to the European and Canadian Practice Guidelines (Fig. 93–2). All patients should be encouraged to initiate and maintain a heart healthy lifestyle, including a low fat diet, high intake of plenty of fresh fruits and vegetables, regular physical exercise, and no smoking. Specific treatment options include watchful waiting, pharmaco logical therapy, and surgical intervention. Although phytotherapy is used by some patients alone or along with conventional medications for BPH, head-to-head comparisons with U.S. Food and Drug Administration (FDA)-approved treatments are lacking; consequently, such herbal cannot be recommended at this time.

Patients with mild disease are asymptomatic or have mildly bothersome symptoms and have no complications of BPH disease. For these patients, no specific treatment is indicated. These patients can be managed with watchful waiting, which entails having the patient return for reassessment at yearly intervals. At each return visit, the patient should complete a standardized, validated survey tool to assess severity of symptoms. Watchful waiting should be accompanied by patient education about the disease and behavior modification to avoid practices that exacerbate voiding symptoms. Behavior modification includes restricting fluids close to bedtime, minimizing caffeine and alcohol intake, frequent emptying of the bladder during waking hours (to avoid overflow incontinence and urgency), and avoiding drugs that could exacerbate voiding symptoms. At each visit, physicians should assess the patient’s risk of developing acute urinary retention by evaluating the patient’s prostate size or using PSA as a surrogate marker of prostate enlargement.

If symptoms progress to the moderate or severe level, or the patient perceives his symptoms to be bothersome, the patient should be offered specific treatment. In these patients, watchful waiting delays—but does not decrease—the need for prostatectomy. In symptomatic patients, watchful waiting can lead to intractable urinary retention, increased PVR urine volumes, and significant voiding symptoms. Recommended treatment options include drug therapy with an α2-adrenergic antagonist or 5α-reductase inhibitor, a combination of an α2-adrenergic antagonist and a 5α-reductase inhibitor, or surgery.

Patients with serious complications of BPH should be offered surgical correction (transurethral or open prostatectomy, or a minimally invasive surgical procedure). Drug therapy is considered an interim measure for such patients because it only delays worsening of complications and the need for surgical intervention.

### PHARMACOLOGIC THERAPY

Drug therapy for BPH can be categorized into three types: agents that relax prostatic smooth muscle (reducing the dynamic factor), agents that interfere with testosterone’s stimulatory effect on prostate gland enlargement (reducing the static factor), and combination therapy of an α1-adrenergic antagonist and a 5α-reductase inhibitor (Table 93–2). Of the agents that relax prostatic smooth muscle, second- and third-generation α1-adrenergic antagonists have been most widely used. These agents relax the intrinsic urethral sphincter and prostatic smooth muscle, thereby enhancing urinary outflow from the bladder. α1-Adrenergic antagonists do not reduce prostate size. Of the agents that interfere with testosterone’s stimulatory effect on prostate gland size, the only agents approved by the FDA are 5α-reductase inhibitors (e.g., finasteride, dutasteride). Other agents that interfere with androgen stimulation of the prostate have not been popular in the United States because of the many adverse effects associated with their use. The luteinizing hormone-releasing

hormone superagonists leuprolide and goserelin decrease libido and can cause erectile dysfunction, gynecostasia, and hot flashes. Antiandrogens (e.g., bicalutamide, flutamide) produce nausea, diarrhea, and hepatotoxicity.

Selection of a medical treatment for a patient should be determined on a case-by-case basis after patient and provider discussion of risks, benefits, and costs of various treatments. With drug therapy for BPH, patients must understand that the benefits continue only as long as the medication is taken.

If possible, drug therapy should be initiated with a single agent, usually an α1-adrenergic antagonist, which is faster acting and more effective than a 5α-reductase inhibitor. In addition, α1-adrenergic antagonists are effective in reducing LUTS independent of prostate size, have no effect on PSA, and are associated with less sexual dysfunction than are 5α-reductase inhibitors. A 5α-reductase inhibitor is a good first-choice agent for patients with a significantly enlarged prostate (＞40 g) who can not tolerate the cardiovascular adverse effects of α1-adrenergic antagonists. For patients at risk for developing complications of BPH, specifically patients with an enlarged prostate gland greater than 40 g, and an elevated PSA ≥1.4 ng/mL, a combination drug therapy with an α1-adrenergic antagonist and a 5α-reductase inhibitor is more beneficial than single drug therapy. The pharmacologic rationale for such a combination is that using two drugs with different mechanisms of action can be more effective than either drug alone. The clinical benefit of combination therapy is that it quickly relieves symptoms, delays disease progression and reduces the need for surgical intervention.

**α1-Adrenergic Antagonists**

Three generations of α1-adrenergic antagonists have been used to treat BPH. They all relax smooth muscle in the prostate and bladder neck. Because of their antagonism of presynaptic α2-adrenergic receptors that result in tachycardia and arrhythmias, first-generation agents such as phenoxybenzamine have been replaced by the second-generation postsynaptic α1-adrenergic antagonists and third-generation uroselective postsynaptic α1-adrenergic antagonists.

The second- and third-generation α1-adrenergic antagonists are considered equally effective for treatment of BPH. These agents generally improve the AUA Symptom Score by 30% to 40% within 2 to 6 weeks, depending on the need for up dose titration, increase urinary flow rate by 2 to 3 mL/s in 60% to 70% of treated patients, and reduce PVR urine volume. They have no effect on decreasing prostate volume. Finally, α1-adrenergic antagonists do not reduce PSA levels, preserving the utility of this prostate cancer marker in this high-risk population.

Second-generation agents include prazosin, terazosin, doxazosin, and alfuzosin. At the usual doses used to treat BPH, prazosin, terazosin, and doxazosin antagonize peripheral vascular α1-adrenergic receptors in addition to those in the prostate. As a result, first-dose syncope, orthostatic hypotension, and dizziness are characteristic adverse effects. To improve tolerance to these adverse effects, therapy should start with a low dose of 1 mg daily and then should be slowly titrated up to a full therapeutic dose over several weeks. Additive blood-pressure-lowering effects commonly occur when these agents are used with antihypertensive agents, which limit use of these agents for some patients. These agents differ in terms of duration of action and dosage formulation. Whereas prazosin requires dosing two to three times per day, terazosin, doxazosin, and alfuzosin offer more convenient once daily dosing. Because prazosin requires twice to thrice daily dosing and has significant cardiovascular adverse effects, it is not recommended in the current AUA guidelines for treatment of BPH. Extended-release dosage formulations are available for doxazosin and alfuzosin. These offer the convenience of once daily dosing, treatment initiation with a full therapeutic dose, and decreased dose-related hypotension as the formulation produces lower peak serum concentrations than immediate-release products. An α1-adrenergic antagonist is not preferred as single-drug therapy for treatment of both BPH and hypertension in a patient. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) of 24,000 patients with hypertension, doxazosin produced more congestive heart failure than amiodipine, lisinopril, or chlorthalidone. Thus, both the AUA and the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure recommend that patients with BPH and hypertension be treated with separate and appropriate drug treatment for each medical condition.

Alfuzosin is considered functionally and clinically uroselective in that usual doses used to treat BPH are less likely than other second-generation agents to cause cardiovascular adverse effects in animal or human models. This clinical observation has been seen more often with the once daily, extended-release formulation of alfuzosin, which is the only commercially available formulation in the United States, as compared with the immediate-release formulation that is dosed three times per day, which is available in Europe. Its clinical uroselectivity has been postulated to be due to higher concentrations of alfuzosin achieved in the prostate versus serum after usual doses, decreased blood–brain barrier penetration of alfuzosin, absence of high peak serum levels with the extended-release formulation, and fixed dosing schedule of the extended-release formulation. Extended-release alfuzosin dosing is FDA approved for 10 mg daily, with no dose titration increase. This formulation is particularly convenient for physician prescribers and patients who are starting to take the medication.

Tamsulosin and silodosin are the only third-generation α1-adrenergic antagonists available in the United States. They are an advance over second-generation agents in that they are selective for prostatic α1A-adrenergic receptors, which comprise approximately 70% of the adrenergic receptors in the prostate gland. Blockade of these receptors results in smooth muscle relaxation of the prostate and bladder neck without causing peripheral vascular smooth muscle relaxation. Tamsulosin and silodosin have low affinity for vascular α1D-adrenergic receptors, which explains why hypotension is not a common adverse effect.

Tamsulosin’s selectivity for α1A-adrenergic receptors has multiple implications. Dose titration is minimal; therefore, patients can begin therapy with the lowest effective maintenance dose of 0.4 mg/day taken orally. Patients can be instructed to take the dose anytime during the day, unlike immediate-release formulations of terazosin and doxazosin, which should be taken at bedtime so that patients can sleep through the time when peak cardiovascular adverse effects are most likely to occur. However, for best oral absorption, tamsulosin should be taken on an empty stomach because food decreases the drug’s bioavailability and reduces the peak serum concentration of the drug after dosing. The onset of peak action is quick, in the range of 1 week, and only a minority of patients will require up titration to a higher daily dose. No decreases in blood pressure or increases in heart rate have been reported in normotensive patients, the elderly, subgroups of patients with well-controlled hypertension, or those with uncontrolled hypertension. Thus, tamsulosin allows initiation of treatment with a therapeutic dose that is not limited by cardiovascular adverse effects, unlike immediate-release formulations of terazosin and doxazosin. Finally, the addition of tamsulosin to select antihypertensive regimens of patients does not result in potentiation of the hypotensive effect of furosemide, enalapril, nifedipine, and atenolol. Therefore, tamsulosin is a good choice, particularly for patients who can not tolerate hypotension; have severe coronary artery disease, volume depletion, cardiac...

arrhythmias, severe orthostasis, or liver failure; are taking multiple antihypertensives; or when the titration would be too complicated for the patient or produce an unacceptable delay in onset for a particular patient.

As compared with tamsulosin, silodosin requires dosage modification for patients with renal and hepatic impairment, has the potential for more drug interactions with inhibitors of CYP 3A4 (e.g., clarithromycin) and P-glycoprotein (e.g., cyclosporine), and has much less clinical experience with its use for patients with cardiovascular disease. For these reasons, tamsulosin is the preferred third-generation α₁-adrenergic antagonist in clinical practice.²¹

The usual doses of α₁-adrenergic antagonists are summarized in Table 93–3.

When using immediate-release formulations of the second-generation α₁-adrenergic antagonists terazosin and doxazosin, slow titration up to a therapeutic maintenance dose is necessary to minimize orthostatic hypotension and first-dose syncope. Conservatively, dosages should be increased in an orderly stepwise process, at 2- to 7-day intervals, depending on the patient’s response to the medication. A faster titration schedule can be used as long as the patient does not develop orthostatic hypotension or dizziness. Two sample titration schedules for terazosin are as follows:

• **Schedule 1: Slow titration**

  Days 4 to 14: 2 mg at bedtime  
  Weeks 2 to 6: 5 mg at bedtime  
  Weeks 7 and on: 10 mg at bedtime

• **Schedule 2: Quicker titration**

  Days 1 to 3: 1 mg at bedtime  
  Days 4 to 14: 2 mg at bedtime  
  Weeks 2 to 3: 5 mg at bedtime  
  Weeks 4 and on: 10 mg at bedtime

Patients should continue taking the drug as long as they continue to respond to it. Durable responses for 6 and 10 years have been reported for tamsulosin and doxazosin, respectively. If BPH symptoms worsen despite maximum tolerable drug doses, surgery should be considered.

With the exception of silodosin, no dosage adjustments are recommended for α₁-adrenergic antagonists for patients with renal failure. Because these drugs are hepatically catabolized, the lowest effective dose should be used for patients with hepatic dysfunction, and patients should be monitored carefully for adverse effects. With the exception of silodosin, no specific dosing guidelines for this patient population are available. For silodosin, a reduced daily dose of 4 mg is recommended for patients with moderate renal impairment or those with hepatic dysfunction.

Approximately 10% to 12% of patients discontinue taking second-generation α₁-adrenergic antagonists because of adverse effects, especially those that affect the cardiovascular system (e.g., syncope, dizziness, hypotension).³⁹ Patients who tolerate hypotension poorly should avoid second-generation α₁-adrenergic antagonists. This includes patients with poorly controlled angina, serious cardiac arrhythmias, patients with reduced circulating volume, and patients taking multiple antihypertensives.³⁹ These patients are candidates for a third-generation α₁-adrenergic antagonist or finasteride, if drug therapy is deemed necessary. Whether extended-release alfuzosin or silodosin is a good choice remains to be elucidated in controlled comparison trials with tamsulosin.⁴⁰–⁴³

Tiredness and asthenia, ejaculatory dysfunction, flu-like symptoms, and nasal congestion are the most common dose-related adverse effects of tamsulosin and silodosin.⁴² These adverse effects are extensions of their α₁-adrenergic antagonist activity and are unavoidable, but with proper education patients likely will not discontinue treatment.

Floppy iris syndrome has been associated with doxazosin, silodosin, and tamsulosin use, although the number of reported cases is highest with tamsulosin.⁴²,⁴³ The mechanism for this adverse reaction is related to blockade of α₁₁-adrenergic receptors in iris dilator muscles. As a result, during cataract surgery, papillary constriction occurs and the iris billows out (floppy iris), both of which complicate the procedure or can increase the likelihood of postoperative complications.⁴²–⁴⁵ Patients who are taking α₁-adrenergic antagonists and who plan to undergo cataract surgery should inform their ophthalmologist that they are taking this medication so that appropriate measures can be taken during eye surgery, e.g., use of iris retractors, papillary expansion rings, or potent mydriatic agents.⁴³ Patients with severe sulfa allergy should avoid tamsulosin.

Caution is needed when CYP 3A4 inhibitors, e.g., cimetidine, diliazem are used with α₁-adrenergic antagonists because a drug–drug interaction could lead to decreased metabolism of the latter agents. In contrast, concurrent use of potent CYP 3A4 stimulators, e.g., carbamazepine and phenytoin, may increase hepatic catabolism of α₁-adrenergic antagonists.

Phosphodiesterase inhibitors (e.g., sildenafil, vardenafil, tadalafil) may produce systemic hypotension if used in large doses along with α₁-adrenergic antagonists. The mechanisms for this interaction are related to the intrinsic vasodilatory effects of phosphodiesterase inhibitors and the higher susceptibility of elderly patients to venous pooling because of autonomic incompetence.⁴²–⁴⁶ Therefore, package labeling for these drugs includes a caution to carefully monitor patients who are taking phosphodiesterase inhibitors with α₁-adrenergic antagonists.

**CURRENT CONTROVERSY**

Among the α₁-adrenergic antagonists, tamsulosin and extended-release alfuzosin have been associated with the highest and lowest incidences of ejaculatory dysfunction, respectively. Although some clinicians claim that this difference should be considered when selecting one agent over another, this adverse effect is of variable clinical significance. Some patients complain of decreased sexual satisfaction because of ejaculatory dysfunction, whereas other patients do not.
5α-Reductase Inhibitors

Finasteride competitively inhibits type II 5α-reductase, suppresses intraprostatic DHT by 80% to 90%, and decreases serum DHT levels by 70%. Dutasteride is a nonselective inhibitor of type I and II 5α-reductase. It more quickly and completely suppresses intraprostatic DHT production and decreases serum DHT levels by 90%. However, direct comparison clinical trials show no advantages of these pharmacodynamic actions of dutasteride when compared with finasteride. These agents are indicated for management of moderate to severe BPH disease for patients with enlarged prostate glands of at least 40 g. For such patients, 5α-reductase inhibitors may slow disease progression and decrease the risk of disease complications, thereby decreasing the ultimate need for surgical intervention. When taken continuously for 6 years, finasteride has been shown to decrease the risk of acute urinary retention and prostatectomy. For patients with severe disease, these agents generally can be used with a 6-month short course of an α1-adrenergic antagonist, which will provide fast symptom relief until the 5α-reductase inhibitor starts to work. 5α-Reductase inhibitors may be preferred for patients with BPH and an enlarged prostate gland who have uncontrolled arrhythmias, have poorly controlled angina, are taking multiple antihypertensive agents, or are unable to tolerate hypotensive adverse effects of α1-adrenergic antagonists.

5α-Reductase inhibitors reduce prostate size by 25%, increase peak urinary flow rate by 1.6 to 2.0 mL/s, improve voiding symptoms in approximately 30% of treated patients, and produce few serious adverse effects. Compared with α1-adrenergic antagonists, 5α-reductase inhibitors have several disadvantages. 5α-Reductase inhibitors have a delayed peak onset of clinical effect, which is undesirable for patients with bothersome symptoms, and an adequate clinical trial is 6 to 12 months. In addition, the percentage of patients who experience objective improvement is less with 5α-reductase inhibitors than with α1-adrenergic antagonists. 5α-Reductase inhibitors cause more sexual dysfunction than α1-adrenergic receptor antagonists; therefore, physicians consider 5α-reductase inhibitors to be second-line agents for treatment of BPH in sexually active males (Table 93-4).

Patients with BPH who have large prostate glands, PSA level less than 3 ng/mL (3 mcg/L) and are concerned about developing prostate cancer can be prescribed finasteride 5 mg daily for up to 7 years, which has been shown to reduce the 7-year prevalence of prostate cancer by 25% in the Prostate Cancer Prevention Trial. However, in this study, finasteride was associated with a small increased risk of developing a higher-grade prostate cancer, which has a potential for invasiveness. Although originally thought to be an adverse effect of finasteride use, it is now thought that the higher incidence of prostate cancer is due to biopsy sampling bias. That is, since finasteride reduces the size of the prostate gland, this results in increased sensitivity of sampling biopsies to detect prostate cancer. The ongoing Reduction by Dutasteride in Prostate Cancer Events (REDUCE) trial should provide additional information on the value of 5α-reductase inhibitors in preventing prostate cancer.

Finasteride is well absorbed from the gastrointestinal tract (95%), and its absorption is unaffected by food. Peak serum concentrations are reached 1 to 2 hours after the dose. Finasteride is highly protein bound. The liver extensively metabolizes finasteride to inactive metabolites, which are largely excreted in stool. The plasma half-life is 4.7 to 7.1 hours, but its biologic half-life probably is longer, as decreased serum DHT levels persist for up to 2 weeks after finasteride dosing is stopped.

For BPH, finasteride is given in doses of 5 mg by mouth daily. The dose can be taken with meals or on an empty stomach. No dosage adjustment is needed for patients with renal dysfunction. Although no dosage reduction is recommended for patients with hepatic insufficiency, patients should be monitored carefully. Maximal reductions in prostate volume or symptom improvement may not be evident for 12 months, but noticeable changes from baseline should occur after 6 months of continuous treatment. No clinically relevant drug interactions have been reported with 5α-reductase inhibitors.

Patients must continue to take 5α-reductase inhibitors as long as they respond. Durable responses to finasteride and dutasteride have been reported with continued treatment for 6 years and 4 years, respectively. Upon discontinuation of the drug, prostate size and voiding symptoms generally return to baseline.

5α-Reductase inhibitors can produce sexual dysfunction, and this has led to discontinuation of therapy in up to 12% of treated patients in one pooled analysis. Ejaculation disorders (dry sex or delayed ejaculation) have been reported in 3% to 8% of treated patients. These disorders, which are possible results of decreased production of nitric oxide, a vasodilatory substance) in cavernosal tissue, may be secondary to ejaculation disorders or may be due to drug-induced inhibition of nitric oxide synthase (which is needed to produce nitric oxide, a vasodilatory substance) in cavernosal tissue. The role of 5α-reductase inhibitors in causing erectile dysfunction is not clear, as elderly men with BPH commonly develop erectile dysfunction as they age or have concurrent medical illnesses or concomitant drug therapies that may predispose to the development of sexual dysfunction. Decreased libido has been reported in 2% to 10% of treated patients.

Other minor adverse effects include nausea, abdominal pain, asthenia, dizziness, flatulence, headache, rash, muscle weakness, and gynecomastia.

5α-Reductase inhibitors are in FDA pregnancy category X, which means that they are contraindicated in pregnant females. Exposure of the male fetus to finasteride may produce pseudohermaphroditic offspring with ambiguous genitalia, similar to those of patients with a rare genetic deficiency of type II 5α-reductase. Because of this teratogenic effect, women who are pregnant or seeking to become pregnant should not handle 5α-reductase inhibitor tablets and should not have contact with semen from men being treated with 5α-reductase inhibitors. Women pharmacists of childbearing age should handle this product with rubber gloves if there is any chance that they are pregnant.

Usual doses of 5α-reductase inhibitors produce a median reduction of serum PSA levels by 50%. For this reason, PSA levels must

* Motivation is a quantitative assessment, for example 5α-reductase inhibitors cause more types of several dysfunction than α1-adrenergic antagonists.
be measured before treatment begins, and the patient should have a digital rectal examination. After 6 months of therapy, the patient should have a repeat PSA. If the level does not decline by 50% and the patient has been adherent to the 5α-reductase inhibitor regimen, he should be evaluated for prostate cancer. Annually thereafter, the patient should have a PSA assay and digital rectal examination, and patients with an increase in PSA levels should be evaluated for prostate cancer or noncompliance to the prescribed regimen. To interpret a PSA level in a patient being treated with a 5α-reductase inhibitor, it is generally recommended that the actual measured level be doubled to get an estimate of the true level.11,55

**CURRENT CONTROVERSY**

Dutasteride is a nonselective 5α-reductase inhibitor that more quickly and effectively lowers intraprostatic DHT production and lowers plasma DHT levels than finasteride does. Whether these hormonal changes result in clinical advantages over finasteride remains to be elucidated.47–48

**CURRENT CONTROVERSY**

The combination of an α1-adrenergic antagonist and 5α-reductase inhibitor can relieve LUTS, slow progression of BPH, and reduce the need for prostate surgery for patients with moderate to severe symptoms and a prostate of 40 g or larger. It may be possible to discontinue the α1-adrenergic antagonist after the first several months; however, this potentially cost-saving measure requires further clinical study.

**Combination Therapy**

Combination therapy with an α1-adrenergic antagonist and a 5α-reductase inhibitor is ideal for patients with severe symptoms, who also have an enlarged prostate gland of at least 40 g and PSA of at least 1.4 ng/mL (1.4 μg/L), a surrogate marker for an enlarged prostate gland.44–47 Such patients appear to be at high risk for disease progression, as evidenced by symptom worsening and development of disease complications.4 A regimen of finasteride and doxazosin for 5 years was shown to prevent symptom progression by 66%, decrease the risk of developing acute urinary retention by 81%, and decrease the need for prostate surgery by 67%.13 In preliminary findings from a clinical trial of dutasteride versus tamsulosin versus the combination of dutasteride and tamsulosin for patients with large prostate glands (i.e., mean prostate volume of 55 ± 23 cc (55 ± 23 mL) and mean PSA of 4 ng/mL [4 mcg/L]), the combination drug regimen was more effective in reducing symptoms than dutasteride alone or tamsulosin alone. Whether the combination of dutasteride and tamsulosin prevents disease progression awaits long-term study results.68 Although not proven by direct comparison trials, any combination of 5α-reductase inhibitor and α1-adrenergic antagonist probably is similarly effective for patients with the aforementioned characteristics.13 The disadvantages of a combination regimen include increased medication cost to the patient and an increased incidence of adverse drug effects (i.e., 18% to 27% of patients discontinued treatment due to hypotension).

**Use of Anticholinergic Agents for Patients with BPH**

Treatment with an α1-adrenergic antagonist, 5α-reductase inhibitor, or surgery may improve urinary flow rate and bladder emptying; however, the patient may still complain of irritative voiding symptoms (e.g., urinary frequency, urgency), which mimic those of overactive bladder syndrome. Oxybutynin and tolterodine have been used to relieve these symptoms. By blocking muscarinic receptors in the detrusor muscle, these agents can reduce uninhibited detrusor contractions, a sequela of prolonged bladder outlet obstruction from BPH. Thus, they can reduce urinary frequency and urgency. Because elderly patients are sensitive to the central nervous system adverse effects and dry mouth associated with anticholinergic agents, patients should be started on the lowest effective dose and then slowly titrated up.55–59 Similarly in the presence of BPH, anticholinergic agents can rarely cause acute urinary retention. Therefore, prescribing anticholinergic agents should be done cautiously, and patients monitored closely.

**SURGICAL INTERVENTION**

The gold standard for treatment of patients with complications of BPH is prostatectomy performed either transurethrally or as an open surgical procedure.11,12 Surgical intervention is also used for patients with moderate to severe symptoms, who are not responsive to drug therapy, who are noncompliant with drug therapy, or who prefer surgical intervention. Surgical removal of the prostate offers the highest rate of symptom improvement, but it also has the highest complication rate.

With transurethral resection of the prostate (TURP), an endoscopic resectoscope inserted through the urethra is used to remove the inside core of the prostate. This enlarges the urethral opening at the bladder neck. TURP is performed only in men with enlarged prostates that are less than 50 g so that the resection can be completed in less than 1 hour. Often performed as outpatient surgery, this procedure produces on average a peak urinary flow rate increase of 125% and improvement of voiding symptoms by almost 90% in approximately 90% of patients.16 A common complication of TURP is retrograde ejaculation, occurring in up to 75% of patients. Significant bleeding, urinary incontinence, and erectile dysfunction occur in smaller but significant numbers of patients (2% to 15%).60,61 Approximately 2% to 10% and 12% to 15% of patients require second surgeries within 5 and 8 years, respectively.60

Men with larger prostates (>50 g) require an open surgical procedure (open prostatectomy), which can be performed retroperitoneally or suprapubically. This necessitates hospitalization for at least a few days, anesthesia, and a longer recuperation time. Adverse effects of open prostatectomy include bleeding, urinary and soft-tissue infection, retrograde ejaculation in 77% of patients, erectile dysfunction in 16% to 33% of patients, and urinary incontinence in 2% of patients. The reoperation rate is 3% to 5% at 10 years.11

Transurethral incision of the prostate (TUIP) is an alternative surgical procedure for patients with moderate to severe voiding symptoms who have an enlarged prostate gland less than 30 g in size. In the short term TUIP is as effective as TURP but requires less operation time, causes less blood loss, and produces fewer adverse effects.11 TUIP involves using an endoscopic resectoscope to make two or three incisions at the bladder neck to widen the opening. In limited long-term studies, the reoperation rate for TUIP is slightly higher than with TURP.

Minimally invasive surgical procedures are highly desirable by patients. The procedures are short (lasting minutes), have a lower potential to produce adverse effects, are less expensive than continuous drug therapy lasting years, and they may be particularly useful in debilitated patients who are poor surgical candidates. The ideal candidates have moderate to severe voiding symptoms with smaller sized prostate glands. These procedures typically use heat energy from microwaves, water, or laser to destroy prostate.
and third-generation agents include tamsulosin and silodosin. Immediate-release formulations of terazosin and doxazosin cause more cardiovascular adverse effects than do extended-release doxazosin or alfuzosin, tamsulosin, or silodosin. Whether extended-release doxazosin, extended-release alfuzosin, or silodosin are as well tolerated as tamsulosin for patients at risk for hypotension or hypotension-related morbidity remains to be elucidated. 5α-Reductase inhibitors are preferred drug treatment for patients with enlarged prostates who poorly tolerate the hypotensive adverse effects of α1-adrenergic antagonists. However, 5α-reductase inhibitors have a slow onset of action. For patients who do not respond to monotherapy, combination drug therapy could be attempted. Such regimens have been found to be most effective for patients with enlarged prostates greater than 40 g. Alternatively, surgery is an option.

For patients who have complications of BPH, surgery is required. Although it has more adverse complications than does pharmacotherapy or watchful waiting, TURP is considered the gold standard.

**ABBREVIATIONS**

AUA: American Urological Association
BPH: benign prostatic hyperplasia
BUN: blood urea nitrogen
DHT: dihydrotestosterone
LUTS: lower urinary tract symptoms
PSA: prostate-specific antigen
PVR: postvoid residual
TUIP: transurethral incision of the prostate
TURP: transurethral resection of the prostate

Urinary Incontinence

ERIC S. ROVNER, JEAN WYMAN, THOMAS LACKNER, AND DAVID R.P. GUAY

KEY CONCEPTS

1. In evaluating urinary incontinence, drug-induced or drug-aggravated etiologies must be ruled out.
2. Accurate diagnosis and classification of urinary incontinence type are critical to the selection of appropriate pharmacotherapy.
3. Nonpharmacologic, nonsurgical therapy is the cornerstone of management of several types of urinary incontinence, often should be the first therapy initiated, and should be continued even when drug therapy is initiated.
4. Anticholinergic/antispasmodic agents are the pharmacologic therapies of choice for bladder overactivity (urge incontinence).
5. Duloxetine (not approved for treatment of urinary incontinence in the United States), α-adrenergic receptor agonists, and topical (vaginal) estrogens (alone or together) are the pharmacologic therapies of choice in urethral underactivity (stress incontinence).
6. Patient-specific treatment goals should be identified. They are not static and may change over time. Choice of therapy may be influenced by characteristics such as patient age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen. If therapeutic goals are not achieved with a given agent at optimal dosage, addition of a second agent or switching to an alternative single agent should be considered.

EPIDEMIOLOGY

Determining the true prevalence of UI is difficult because of problems with definition, reporting bias, and other methodologic issues. Epidemiologic studies have not historically used a standard definition of the condition or a standard methodology for data recording, with some studies including “postvoid dribbling,” while other studies specify “urinary leakage causing a social or hygienic problem.” Many people suffer from UI, and the impact of this condition is substantial, crossing all racial, ethnic, and geographic boundaries. Compared with continent controls, patients with UI have an overall poorer quality of life. Several studies have objectively shown that UI is associated with reduced levels of social and personal activities, increased psychological distress, and overall decreased quality of life as measured by numerous indices. The condition can affect people of all age groups, but the peak incidence of UI, at least in women, appears to occur around the age of menopause, with a slight decrease in the age group 55 to 60 years, and then a steadily increasing prevalence after age 65 years.

One of the earliest comprehensive epidemiologic studies on UI was conducted by Diokno et al. using a standardized survey questionnaire. The Medical, Epidemiologic, and Social Aspects of Aging survey found that the prevalence of UI in noninstitutionalized women 60 years of age and older was approximately 38%. Almost one third of those surveyed noted urine loss at least once weekly, and 16% noted UI daily. A publication from a National Institutes of Health working group conference estimated the median level of UI prevalence to be approximately 20% to 30% during young adult life, with a broad peak around middle age (30%–40% prevalence) and an increase in the elderly (30%–50% prevalence). In the United States, chronic UI is one of the most common reasons cited for institutionalization of the elderly, and the condition is frequently encountered in the nursing home setting. Little is known about the basic differences in clinical and epidemiologic characteristics of incontinence across racial or ethnic groups. Some studies report a higher incidence of UI overall in white populations as compared with African Americans, but differences in access to healthcare as well as cultural attitudes and mores may contribute to these differences.

Consistent across all studies of unselected, noninstitutionalized populations is that UI is at least half as common in men as in women. Overall, the prevalence of UI in men has been estimated to be approximately 9%. Unlike in women, the prevalence of UI in men increases with age across most studies, with the highest prevalence recorded in the oldest patient cohorts.
Etiology and Pathophysiology

Anatomy

The lower urinary tract consists of the bladder, urethra, urinary or urethral sphincter, and surrounding musculoskeletal structures, including connective tissue, nerves, and blood vessels. The urinary bladder is a hollow organ composed of smooth muscle and connective tissue located deep in the bony pelvis in men and women. The urethra is a hollow tube that acts as a conduit for urine flow out of the bladder. The interior surface of both the bladder and the urethra is lined by an epithelial layer termed the transitional epithelium, which is in constant contact with urine. Previously considered inert and inactive, transitional epithelium may play an active role in the pathophysiology of many lower urinary tract disorders, including interstitial cystitis and UI.

The urinary or urethral sphincter is a combination of smooth and striated muscle within and surrounding the most proximal portion of the urethra adjacent to the bladder in both men and women. This is a functional but not anatomic sphincter that includes a portion of the bladder neck or outlet as well as the proximal urethra.

Urinary Continence

To prevent incontinence during the bladder filling and storage phase of the micturition cycle, the urethra, or more accurately the urethral sphincter, must maintain adequate closure in order to resist the flow of urine from the bladder at all times until voluntary voiding is initiated. Urethral closure or resistance to flow is maintained to a large degree by the proximal (under involuntary control) and distal (under both voluntary and involuntary control) urinary sphincters, a combination of smooth and striated muscles within and external to the urethra. Variable contributions to urethral closure may also come from the urethral mucosa, submucosal sponge tissue, and the overall length of the urethra. During bladder filling and storage, the bladder accommodates increasing volumes of urine flowing in from the upper urinary tract without a significant increase in bladder (intravesical) pressure. The maintenance of a low intravesical pressure despite increasing volumes of urine is a unique property of the bladder and is termed compliance. In addition, bladder or detrusor smooth muscle activity is normally suppressed during the filling phase by centrally mediated neural reflexes. Normal bladder emptying occurs with opening of the urethra concomitant with a volitional bladder contraction.

Bladder contraction occurs in a coordinated fashion, resulting in a rise in intravesical pressure. The rise in intravesical pressure is ideally of adequate magnitude and duration to empty the bladder to completion. Opening and funneling of the bladder outlet results in urine flow into the urethra until the bladder is emptied to near completion.

The primary motor input to the detrusor muscle of the bladder is along the pelvic nerves emanating from spinal cord segments S2 to S4. Parasympathetic impulses travel to the bladder along the efferent fibers of the pelvic nerves. The impulses pass through ganglia situated in the bladder wall before reaching their target. Acetylcholine appears to be the primary neurotransmitter at the neuromuscular junction in the human lower urinary tract. Both volitional and involuntary contractions of the detrusor muscle are mediated by activation of postsynaptic muscarinic receptors by acetylcholine. Of the five known subtypes of muscarinic receptors, the majority of bladder smooth muscle cholinergic receptors are of the M3 variety. In humans, the ratio of M3/M1 receptor numbers is approximately 3:1. However, M3 receptors are the subtype responsible for both emptying contractions of normal micturition as well as involuntary bladder contractions that may result in UI. Thus most pharmacologic antimuscarinic therapy is primarily anti-M3 based.

This description of the mechanisms of urinary continence is a bit simplistic. Many other neurohumoral pathways and mechanisms, both within and outside the urinary tract, may play substantial roles in urinary continence (and voiding dysfunction) and may be future therapeutic options for treatment of voiding dysfunction and UI. Examples include adrenergic, purinergic, serotoninergic, and dopaminergic pathways, tachykinin receptor antagonists, and calcium and potassium channel modulators.

The bladder and urethra normally operate in unison during the bladder filling and storage phase, as well as the bladder emptying phase of the micturition cycle. The smooth and striated muscles of the bladder and urethra are organized during the micturition cycle by a number of reflexes coordinated at the pontine micturition center in the midbrain. Disturbances in the neural regulation of micturition at any level (brain, spinal cord, or pelvic nerves) often lead to characteristic changes in lower urinary tract function that may result in UI.

Mechanisms of Urinary Incontinence

Simply stated, UI may occur as a result of abnormalities of only the urethra (including the bladder outlet and urinary sphincter) or only the bladder or as a combination of abnormalities in both. Abnormalities may result in either overfunction or underfunction of the bladder and/or urethra, with resulting development of UI. Although this simple classification scheme excludes extremely rare causes of UI such as congenital ectopic ureters and urinary fistulas, it is useful for gaining a working understanding of the condition.

Urethral Underactivity (Stress Urinary Incontinence)

Some patients characteristically note UI during exertional activities such as exercise, running, lifting, coughing, and sneezing. This implies that the compromised urethral sphincter is no longer able to resist the flow of urine from the bladder during periods of physical activity. In essence, increases in intraabdominal pressure during physical activity are transmitted to the bladder (an intraabdominal organ), compressing it and forcing urine through the weakened sphincter.

This type of UI is known as stress urinary incontinence (SUI). Although the exact etiology of urethral underactivity and SUI in women is incompletely understood, clearly identifiable risk factors include pregnancy, childbirth, menopause, cognitive impairment, obesity, and age. The prevalence of SUI in women appears to peak during or after the onset of menopause. This implies that hormonal factors are important in maintaining continence.

In men, SUI is most commonly the result of prior lower urinary tract surgery or injury, with resulting compromise of the sphincter mechanism within and external to the urethra. Radical prostatectomy for treatment of adenocarcinoma of the prostate is probably the most common setting in which surgical manipulation leads to UI. Overall, SUI in the male is uncommon and, in the absence of prior prostate surgery, severe trauma, or neurologic illness, is extraordinarily rare. Transurethral resection of the prostate for benign prostatic hyperplasia (BPH; see Chap. 93) may lead to SUI in men.

Bladder Overactivity (Urgo Urinary Incontinence)

Bladder overactivity may occur during bladder filling and urine storage due to involuntary bladder (detrusor) contractions. Symptoms of bladder overactivity occur because the detrusor muscle is overactive and contracts inappropriately during the filling phase which, in the neurologically normal individual, results in a sense of urinary urgency. The terms overactive bladder and detrusor overactivity are distinct and should not be used interchangeably, as they frequently are. The International Continence Society defines overactive bladder as a symptom syndrome characterized by urinary urgency, with frequency and nocturia, with/without associated UI in the absence of a known pathologic condition that may result in similar symptoms.
(e.g., urinary tract infection, bladder cancer).1 When UI occurs concomitantly with a sense of urinary urgency, it is termed urge urinary incontinence (UUI).1 The latter is most commonly, although not invariably, associated with involuntary detrusor contractions.

Therefore, a diagnosis of overactive bladder does not require urodynamic testing for confirmation but is a diagnosis based on patient symptoms. Conversely, detrusor overactivity is a specific urodynamic diagnosis referring to the finding of involuntary detrusor contractions during the filling phase of a urodynamic study. Therefore, invasive urodynamic testing is required to make the diagnosis. Up to 40% of patients with overactive bladder do not demonstrate detrusor overactivity on urodynamic testing. The clinical significance of this finding is unknown. However, the effectiveness of pharmacologic therapy appears to be independent of the presence or absence of detrusor overactivity.20 This distinction between overactive bladder (a symptom syndrome) and detrusor overactivity (a urodynamic diagnosis) is essential in fully understanding the patient population under study and the effects of pharmacologic therapy reported in the literature.

Symptoms characteristic of overactive bladder are urinary frequency and urgency, with or without urge incontinence. Frequency is defined as micturition more than eight times per day. Urgency is described as a sudden compelling desire to urinate that is difficult to delay.1 People suffering from overactive bladder typically have to empty their bladder frequently, and, when they experience a sensation of urgency, they may leak urine if they are unable to reach the toilet quickly. Many patients have associated nocturia (>1 micturition per night) and/or nocturnal incontinence (enuresis). Nocturia and enuresis are particularly disruptive to sleep. For patients with incontinence, the amount of urine lost may be large, as the bladder may empty completely.

Most patients with overactive bladder and UUI have no identifiable underlying etiology and thus are classified as “idiopathic.” Patients with a relevant neurologic condition and with urinary incontinence related to involuntary bladder contractions demonstrated on urodynamic testing are classified as having neurogenic detrusor overactivity. Clearly identifiable risk factors for UUI include normal aging, neurologic disease (including stroke, Parkinson’s disease, multiple sclerosis, and spinal cord injury), and bladder outlet obstruction (e.g., due to BPH or prostate cancer).

The mechanism for overactive bladder and UUI must be either neurogenic or myogenic. The neurogenic hypothesis ascribes the condition to disease-related changes within the central or peripheral nervous systems.21 The neurogenic hypothesis states that overactive bladder and UUI result from changes within the smooth muscle of the bladder wall itself.22 Precipitating factors, such as bladder outlet obstruction (BOO), can cause partial denervation of smooth muscle, leading to a state of decreased responsiveness to activation of intrinsic nerves but supersensitivity to contractile agonists and direct electrical activation and detrusor overactivity.23 Indeed, overactive detrusor muscle from an individual with BOO may or may not be quite different as compared with the same muscle tissue from an individual with idiopathic or neurogenic detrusor overactivity in terms of many physiologic and anatomic characteristics (including receptor type[s] and density/densities, collagen content, and innervation).24 A full discussion of these differences is beyond the scope of this chapter. Thus, in practice, UUI is difficult to categorize as either neurogenic or myogenic in origin, as these etiologies often seem to be interconnected and complementary.

**Urethral Overactivity and/or Bladder Underactivity (Overflow Incontinence)** Overactive bladder, the result of urethral overactivity and/or bladder underactivity, is an important but uncommon type of UI in both men and women. Overflow incontinence results when the bladder is filled to capacity at all times but is unable to empty, causing urine to leak from a distended bladder past a normal or even overactive outlet and sphincter.

In the setting of urethral overactivity, resistance to the flow of urine during volitional voiding is increased, resulting in functional or anatomic obstruction and incomplete bladder emptying. Clinically and practically, the most common causes of urethral overactivity in men are anatomic urethral obstruction, including that due to BPH and prostate cancer. In women, urethral overactivity is rare but may result from cystocele formation (with resultant kinking or obstruction of the urethra) or surgical overcorrection (iatrogenic obstruction) following anti-SUI surgery. In both men and women, overflow UI may be associated with systemic neurologic dysfunction or diseases, such as spinal cord injury or multiple sclerosis.

Bladder underactivity may result in overflow incontinence. Under certain circumstances, the detrusor muscle of the bladder may become progressively weakened and eventually lose the ability to voluntarily contract. In the absence of adequate contractility, the bladder is unable to empty completely, and large volumes of residual urine are left after micturition. Both myogenic and neurogenic factors have been implicated in producing the impaired contractility seen in this condition. Clinically, overflow incontinence is most commonly seen in the setting of long-term chronic bladder outlet obstruction in men, such as that due to BPH or prostate cancer, diabetes mellitus, or denervation due to radical pelvic surgery, such as abdominopelvic resection or radical hysterectomy.

**Mixed Incontinence and Other Types of Urinary Incontinence** Various types of UI may coexist in the same patient. The combination of bladder overactivity and urethral underactivity is termed **mixed incontinence**. The diagnosis is often difficult because of the confusing array of presenting symptoms. Bladder overactivity may also coexist with impaired bladder contractility. This occurs most commonly in the elderly and is termed **detrusor hyperactivity with impaired contractility**.25

**Functional incontinence** is not caused by bladder- or urethra-specific factors. Rather, in patients with conditions such as dementia or cognitive or mobility deficits, the UI is linked to the primary disease process more than any extrinsic or intrinsic deficit of the lower urinary tract. An example of functional incontinence occurs in the postoperative orthopedic surgery patient. Following extensive orthopedic reconstructions such as total hip arthroplasty, patients are often immobile secondary to pain or traction. Therefore, patients may be unable to access toileting facilities in a reasonable amount of time and may become incontinent as a result. Treatment of this type of UI may involve simple interventions such as placing a urinal or commode at the bedside that allows for uncomplicated access to toileting.

Many localized or systemic illnesses may result in UI because of their effects on the lower urinary tract or the surrounding structures:

- Dementia/delirium
- Depression
- Urinary tract infection (cystitis)
- Postmenopausal atrophic urethritis or vaginitis
- Diabetes mellitus
- Neurologic disease (e.g., stroke, Parkinson’s disease, multiple sclerosis, spinal cord injury)
- Pelvic malignancy
- Constipation
- Congenital malformations

Many commonly used medications may precipitate or aggravate existing voiding dysfunction and UI (Table 94–1).

**CLINICAL PRESENTATION**

UI may present in a number of ways, depending on the underlying pathophysiology. Generally, SUI is considered the most common type of UI and probably accounts for at least a portion of UI in more than half of all incontinent women. Some studies have found that mixed UI (SUI + UUI) is the most common type of UI. However, the proportions of SUI versus UUI versus mixed UI vary considerably with age group and sex of patients studied, study methodology, and a variety of other factors. A complete medical history, including an assessment of symptoms and a physical examination, is essential for correctly classifying the type of incontinence and thereby assuring appropriate therapy.

**CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL UNDERACTIVITY**

**General**
- The patient usually notes UI during activities such as exercise, running, lifting, coughing, and sneezing. Occurs much more commonly in women (seen only in men with lower urinary tract surgery or injury compromising the sphincter).

**Symptoms**
- Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

**Diagnostic Tests**
- Observation of urethral meatus while patient coughs or strains.

**CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO BLADDER OVERACTIVITY**

**General**
- Can have bladder overactivity and UI without urgency if sensory input from the lower urinary tract is absent.

**URINE LEAKAGE**

UI represents a spectrum of severity in terms of both volume of leakage and degree of bother to the patient. To carefully consider the level of patient discomfort when discussing urine leakage, the clinician must probe during the patient interview to accurately determine the precise nature of the problem.

Use of absorbent products, such as panty liners, pads, or briefs, is an obvious point of discussion, but the clinician must keep in mind that use of these products varies among patients. The number and type of pads may not relate to the amount or type of incontinence, as their use is a function of personal preference and hygiene. A high number of absorbent pads may be used every day by a patient with severe, high-volume UI or, alternatively, by a fastidiously hygienic patient with low-volume leakage who simply changes pads often to prevent wetness or odor. Nevertheless, a large number of pads that are described by the patient as “soaked” is indicative of high-volume urine loss.

Regardless of the volume of urine loss, the desire to seek evaluation and therapy for UI in all patients is almost always elective and contingent on the degree of bother to the individual patient. As with the use of absorbent products, patients differ with regard to the amount of urine loss they will tolerate before considering the condition bothersome enough to seek assistance.

**SYMPTOMS**

Under the best of circumstances, UI is difficult to categorize based on symptoms alone (Table 94–2). In a study of patients who appeared to have SUI based on symptoms and patient history,

Signs

A presenting complaint of UI mandates a directed physical examination and a brief neurologic assessment. The workup ideally includes an abdominal examination to exclude a distended bladder, neurologic assessment of the perineum and lower extremities, pelvic examination in women (looking especially for evidence of prolapse or hormonal deficiency), and genital and prostate examination in men.

SUI can usually be objectively demonstrated by having the patient cough or strain during the examination and observing the urethral meatus for a sudden spurt of urine. In women, SUI may be associated with varying degrees of vaginal prolapse, including cystourethrocele (bladder and urethral prolapse), enterocele (small bowel prolapse), rectocele (rectal prolapse), and uterine prolapse. These conditions may have important implications for therapy in that treatment of the prolapse may result in improvement of urinary symptoms.

Perineal skin maceration, erythema, breakdown, and ulceration may be indicative of chronic, severe UI. Patients with chronic incontinence may manifest fungal infections of the skin of the perineum and upper thighs.

In both men and women, digital rectal examination provides an opportunity to check ambient rectal tone and the integrity of the sacral reflex arc (e.g., anal wink) as well as assess the patient’s ability to perform a voluntary pelvic floor muscle contraction (i.e., Kegel exercise), which may be an important factor in deciding on appropriate therapy. In men, a digital examination of the prostate assesses for the presence of prostate cancer, inflammation, and BPH.

A targeted neurologic examination includes assessment of reflexes, rectal tone, and sensory or motor deficits in the lower extremities, which might be indicative of systemic or localized neurologic disease. Neurologic diseases have the potential to affect bladder and sphincter function and thus may have significant implications in the incontinent patient.

Prior Medical or Surgical Illness

UI may present in the setting of concurrent, seemingly unrelated illnesses. New-onset UI may be the initial manifestation of systemic illnesses such as diabetes mellitus, metastatic malignancies, multiple sclerosis, and other neurologic illnesses. Central nervous system disease, or injury above the level of the pons, generally results in symptoms of bladder overactivity and UUI. Spinal cord injury or disease may manifest as bladder overactivity and UUI or as overflow incontinence, depending on the spinal level and completeness of the injury or disease.

Medications may have wide-ranging effects on lower urinary tract function (see Table 94–1). A thorough inquiry into the use of new medications in the setting of recent-onset UI may show a relationship.

Acute UI manifesting in the immediate postoperative setting may be secondary to a number of factors, including surgical manipulation and immobility, and to a number of medications, especially opioid analgesics. In the postoperative setting, acute urinary retention and overflow incontinence are commonly related to the administration of anesthetic agents and/or opioid analgesics in the perioperative period. These agents may have profound effects on bladder contractility that are completely reversible once the agents are metabolized and excreted.

Prior surgery may have effects on lower urinary tract function. UI following prostate surgery in men is highly suggestive of injury to the sphincter and resultant SUI. Pelvic surgery for benign and malignant conditions may result in denervation or injury to the lower urinary tract. This includes bowel surgery and gynecologic procedures. For example, new-onset total UI following gynecologic surgery suggests intraoperative bladder injury and subsequent development of a postoperative vesicovaginal fistula. Radiation therapy to the pelvis for malignant disease (e.g., prostate cancer or...
Urinary Incontinence

TREATMENT

Urinary Incontinence

NONPHARMACOLOGIC TREATMENT

Nonpharmacologic treatment of UI is recommended as the first line of therapy at a primary care level. For patients in whom pharmacologic or surgical management is inappropriate or undesired, nondrug treatment is the only option. Examples of patients who fulfill these criteria include patients who are not medically fit for surgery, those who plan future pregnancies (which may adversely affect long-term surgical outcomes), those with overflow incontinence whose condition is not amenable to surgery or drug therapy, those with comorbid conditions that place them at high risk for adverse effects from drug therapy, those who are delaying surgery or do not want to undergo surgery, and those with mild to moderate symptoms who do not want to take medication.

For additional information on nonpharmacologic interventions for UI, readers are referred to comprehensive literature reviews and consensus opinions of treatment guidelines on nonpharmacologic treatments seen with long-acting forms of oxybutynin (which are due to reduced first-pass metabolism) compared with those of oxybutynin IR compared with oxybutynin XL. 60 Furthermore, adverse effects jeopardize medication adherence and can prevent dose escalation to that needed for optimal benefit.

Emerging evidence suggests that the high incidence of adverse effects, especially dry mouth, with use of oxybutynin IR is largely due to the active metabolite N-desethylxybutynin (DEO), which is generated during extensive first-pass metabolism in the liver and upper gastrointestinal tract. 55 The lower DEO plasma concentrations seen with long-acting forms of oxybutynin (which are due to reduced first-pass metabolism) compared with those of oxybutynin IR may explain the lesser propensity of the long-acting formulations to cause dry mouth and other anticholinergic adverse effects.

Another factor associated with the adverse effects of oxybutynin IR, especially in older patients, is the transient high peak serum oxybutynin plasma concentrations. 56 Oxybutynin IR is best tolerated when the dose is gradually escalated from no more than 2.5 mg twice daily to start, to 2.5 mg three times daily after 1 month, then further increased in increments of 2.5 mg/day every 1 to 2 months until the desired response or the maximum recommended or tolerated dose is attained. The optimal response usually requires no more than 5 mg three times daily (see Table 94–4). 50,57

Adverse effects of oxybutynin IR can sometimes be managed by a dose reduction if this does not significantly compromise drug efficacy. Dry mouth can be relieved by use of sugarless hard candy, gum, or a saliva substitute. Constipation can be minimized by increasing the intake of water, dietary fiber, physical activity such as walking, or laxative therapy. The need for multiple daily dosing of oxybutynin IR can further jeopardize adherence, especially in people who take multiple medications or those who are cognitively impaired.

PHARMACOLOGIC TREATMENT

Urge Urinary Incontinence

Pharmacotherapy is useful when UUI symptoms are not adequately controlled with nonpharmacologic therapies, particularly in patients with low functional bladder capacity, especially individuals who frequently attempt to toilet and are independent or require only limited assistance in toileting. In many cases, the combined use of pharmacotherapy with nonpharmacologic therapy produces a better response than either intervention alone.

Anticholinergic/antispasmodic drugs have proved to be the most effective agents for suppressing premature detrusor contractions, enhancing bladder storage, and relieving UUI symptoms and complications and constitute the pharmacotherapy of first choice for treatment of UUI (Tables 94–4 and 94–5). 29–48 Drugs with anticholinergic activity act by antagonizing muscarinic cholinergic receptors, through which efferent parasympathetic nerve impulses evoke detrusor contraction. Anticholinergics have been demonstrated to improve quality of life, with no significant differences between agents. 49 Women with mixed UI or UUI plus urethritis or vaginitis may benefit from a topical estrogen (alone or in combination with an anticholinergic drug). Patients with irritative symptoms of BPH that persist despite specific BPH treatment may benefit from anticholinergic therapy as well (caution is warranted because these agents may precipitate acute urinary retention).

<tbody>
<tr>
<td><strong>Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate urinary incontinence</strong></td>
<td></td>
<td>Smoking cessation, weight reduction for obese patients with stress and urge incontinence; constipation prevention, caffeine reduction, fluid modification only for those with abnormally high fluid intake</td>
</tr>
<tr>
<td><strong>Scheduling regimens</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Timed voiding</td>
<td>Toileting on a fixed schedule where interval does not change, typically every 2 hours during waking hours</td>
<td>Used for stress, urge, and mixed incontinence in patients with cognitive or physical impairments; used in patients without impairments who have infrequent voiding patterns</td>
</tr>
<tr>
<td>Habit retraining</td>
<td>Scheduled toiletings with adjustments of voiding intervals (longer or shorter) based on patient’s voiding pattern</td>
<td>Used for institutionalized or homebound patients with cognitive or physical impairments; may be used in patients who have diuretic-induced incontinence</td>
</tr>
<tr>
<td>Prompted voiding</td>
<td>Scheduled toiletings that require prompts to void from a caregiver, typically every 2 hours; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting</td>
<td>Used for patients who are functionally able to use toilet or substitute, able to feel urge sensation, and able to request toileting assistance appropriately, primarily used in institutional settings or in homebound patients with an available caregiver</td>
</tr>
<tr>
<td>Bladder training</td>
<td>Scheduled toiletings with progressive voiding intervals; includes teaching urge suppression strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy</td>
<td>Used for stress, urge, and mixed incontinence in patients who are cognitively intact, able to toilet, and motivated to comply with training program</td>
</tr>
<tr>
<td><strong>Pelvic floor muscle rehabilitation</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Pelvic floor muscle exercises (e.g., Kegel exercises)</td>
<td>Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for prevention of stress leakage and urge inhibition</td>
<td>Used for stress, urge, and mixed incontinence in patients who can correctly contract pelvic floor muscles without using accessory muscles; requires cognitively intact and highly motivated patient</td>
</tr>
<tr>
<td>Biofeedback</td>
<td>Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction and/or urge inhibition; home trainers are available (e.g., Myself, DesChutes Medical Products, Bend, OR; Pathway MR-10 or MR-20, Prometheus Group, Dover, NH)</td>
<td>Used for stress, urge, and mixed incontinence in patients who have the capability to learn voluntary control through observation and are motivated; used in conjunction with pelvic floor muscle exercises</td>
</tr>
<tr>
<td>Vaginal weight training</td>
<td>Active retention of increasing vaginal weights (e.g., Step Free Weights, Medgo LLC, Venice, FL); typically used in combination with pelvic floor muscle exercises at least twice per day</td>
<td>Women with stress incontinence who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and have sufficient vaginal vault and introitus to retain cone, and are highly motivated; contraindicated in patients with moderate to severe pelvic organ prolapse</td>
</tr>
<tr>
<td>Acupuncture</td>
<td>Involves insertion of disposable sterile fine stainless steel needles into points on the skin that are thought to suppress or stimulate spinal and/or supraspinal reflexes to the bladder and/or urethra</td>
<td>Used for urge and mixed incontinence and urinary incontinence due to spinal cord injury</td>
</tr>
<tr>
<td>Nonimplantable electrical stimulation</td>
<td>Application of electrical current through vaginal, anal, surface, or fine needle electrodes; used to inhibit bladder overactivity and improve awareness, contractility, and efficacy of pelvic floor muscle contraction; hand-held stimulators for home use are available (e.g., Pathway, Prometheus Group, Dover, NH; Minnova, Empi, St. Paul, MN)</td>
<td>Used for stress, urge, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception; urinary retention, history of cardiac arrhythmia, cardiac pacemakers, implantable defibrillators, pregnant or attempting pregnancy; vaginal or anal electrodes are contraindicated in moderate or severe pelvic organ prolapse</td>
</tr>
<tr>
<td>Extracorporeal magnetic stimulation</td>
<td>Pulsed magnetic stimulation to pelvic floor musculature causing depolarization of motor neurons, thus inducing pelvic floor muscle contraction; stimulation is provided through a specially designed chair that contains a device for producing a pulsing magnetic field (e.g., Neotonus, Inc., Marietta, GA)</td>
<td>Used for treatment of stress, urge, and mixed incontinence; contraindicated in patients with demand cardiac pacemakers or metallic joint replacements; may be useful treatment option when other approaches fail or are not feasible</td>
</tr>
<tr>
<td><strong>Antincontinence devices</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Pessaries</td>
<td>Intravaginal devices designed to support the bladder neck, relieve minor to moderate pelvic organ prolapse, and change pressure transmission to the urethra (e.g., Cooper Surgical (Miles), Trumbull, CT; Mentor Corporation, Santa Barbara, CA)</td>
<td>Used for female stress incontinence and mild to moderate pelvic organ prolapse; in postmenopausal women, topical estrogen therapy is typically prescribed to prevent ulceration and breakdown of vaginal tissue; requires good manual dexterity to manipulate device</td>
</tr>
<tr>
<td>Bed or pant alarms</td>
<td>Sensor devices that respond to wetness; used to awaken or alert individuals via noise or vibrating mechanism (e.g., Nite Train-r, Koregon Enterprises, Inc., Beaverton, OR; Wet Call Alarm, Alimed, Dedham, MA)</td>
<td>Primarily used for nocturnal enuresis in children; system available for monitoring incontinence in home care and institutional environments</td>
</tr>
<tr>
<td>Urethral compression device (men only)</td>
<td>Penile clamp (e.g., Cunningham Incontinence Clamp, Bard Medical, Covington, GA; ActiCuf, GT Urological, Minneapolis, MN; Cook Confinement, Cook Wound/Ostomy/Confinement, Spencer, IN)</td>
<td>Used for male stress incontinence patients who are intact and have good manual dexterity</td>
</tr>
<tr>
<td>External collection devices (men only)</td>
<td>Condom catheter with leg bag</td>
<td>Used in men with urge, stress, and overflow incontinence and in those with functional impairments</td>
</tr>
<tr>
<td>Catheters</td>
<td>Disposable, intermittent urethral catheters and indwelling urethral and suprapubic catheters</td>
<td>Used for overflow incontinence; used in patients who are bed-bound or with significant mobility impairments and severe incontinence; those with terminal illness; those with sacral pressure ulcers until healing occurs</td>
</tr>
</tbody>
</table>

(continued)
oxybutynin XL administration and, probably less importantly, the lower peak plasma drug concentration are believed to be the reasons for fewer dose- and concentration-dependent adverse effects and better patient tolerance with the XL preparation compared with oxybutynin IR.\textsuperscript{33,35,50–52,62–64} Elimination of oxybutynin XL is not known to be altered in patients with renal or hepatic impairment or in geriatric patients (up to age 78 years).\textsuperscript{58} The absence of an effect of advanced age on oxybutynin XL pharmacokinetics is unexpected because clearance of oxybutynin IR is significantly lower (by approximately 50%) in older patients compared with younger individuals.

Controlled studies have demonstrated that oxybutynin XL is significantly more effective than placebo and is as effective as oxybutynin IR in terms of reducing the mean number of UI episodes, restoring continence, decreasing the number of micturitions per day, and increasing urine volume voided per micturition.\textsuperscript{34,50–52,62–64} In short-term studies of up to 12 weeks’ duration, oxybutynin XL was better tolerated than oxybutynin IR, with approximately 7% of patients discontinuing treatment because of adverse effects (compared with approximately 27% of those taking oxybutynin IR).\textsuperscript{30,35,50,51,57,58} The rate and severity of adverse effects did not differ significantly between elderly persons (≥65 years old) and younger adults using the XL preparation. A 12-week study demonstrated the superiority of oxybutynin XL over tolterodine IR in reducing the mean number of weekly incontinence episodes and micturitions.\textsuperscript{43}

In the Overactive Bladder: Performance of Extended-Release Agents (OPERA) trial, oxybutynin XL and tolterodine long-acting (LA) were equally effective in decreasing the mean number of incontinence episodes, but oxybutynin XL was superior in reducing weekly micturition frequency and achieving total dryness.\textsuperscript{53}

### TABLE 94-4 Pharmacotherapeutic Options in Patients with Urinary Incontinence

<table>
<thead>
<tr>
<th>Type</th>
<th>Drug Class</th>
<th>Drug Therapy (Usual Dose)</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Overactive bladder</td>
<td>Anticholinergic agents/antispasmodics</td>
<td>Oxybutynin IR (2.5–5 mg two, three, or four times daily), oxybutynin XL (5–30 mg daily), oxybutynin TDS (3.9 mg/day) (apply one patch twice weekly), oxybutynin gel (1 sachet [100 mg] topically daily), tolterodine IR (1–2 mg twice daily), tolterodine LA (2–4 mg daily), trospium chloride extended release (60 mg daily), solifenacin (5–10 mg daily), darifenacin (7.5–15 mg daily), desipramine (4–8 mg daily)</td>
<td>Anticholinergics are first-line drug therapy (oxybutynin or tolterodine is preferred)</td>
</tr>
<tr>
<td></td>
<td>Tricyclic antidepressants (TCAs)</td>
<td>Imipramine, doxepin, nortriptyline, or desipramine (25–100 mg at bedtime)</td>
<td>TCAs are generally reserved for patients with an additional indication (e.g., depression, neuropathic pain)</td>
</tr>
<tr>
<td></td>
<td>Topical estrogen (only in women with urethritis or vaginitis)</td>
<td>Conjugated estrogen vaginal cream (0.5 g) three times per week for up to 8 months. Repeat course if symptom recurrence, or use estradiol vaginal insert/ring [2 mg (one ring)] and replace after 90 days if needed</td>
<td>Marginally effective for OAB; few adverse effects with vaginal cream and insert</td>
</tr>
<tr>
<td>Stress</td>
<td>Duloxetine \textsuperscript{a}</td>
<td>40–80 mg/day (one or two doses)</td>
<td>Even though not FDA approved, duloxetine is first-line therapy; most adverse events diminish with time, so support patient during initial period of use</td>
</tr>
<tr>
<td></td>
<td>α-Adrenergic agonists</td>
<td>Pseudoephedrine (15–60 mg three times daily) with food, water, or milk Phenylephrine (10 mg four times daily)</td>
<td>Pseudoephedrine and phenylephrine are alternative first-line therapies for women with no contraindication (notably hypertension); phenylephrine was the preferred agent in the class until its removal from the U.S. market in 2000</td>
</tr>
<tr>
<td></td>
<td>Estrogen</td>
<td>See estrogens (above). Works best if urethritis or vaginitis due to estrogen deficiency is present</td>
<td>Considered a less-effective alternative to α-adrenergic agonists and duloxetine. Combined α-adrenergic agonist and estrogen may be somewhat more effective than α-adrenergic agonist alone in postmenopausal women</td>
</tr>
<tr>
<td></td>
<td>Imipramine</td>
<td>25–100 mg at bedtime</td>
<td>Imipramine is an optional therapy when first-line therapy is inadequate</td>
</tr>
<tr>
<td>Overflow (atonic bladder)</td>
<td>Cholinomimetics</td>
<td>Bethanechol (25–50 mg three or four times daily) on an empty stomach</td>
<td>Avoid use if patient has asthma or heart disease; Short-term use only. Never give IV or IM because of life-threatening cardiovascular and severe gastrointestinal reactions</td>
</tr>
</tbody>
</table>

\textsuperscript{a}Not FDA-approved for this use. Doses provided are those best supported by clinical trials to date.

IR, immediate-release; LA, long-acting; TDS, transdermal system; XL, extended-release.
Due to the absence of information regarding dizziness for oxybutynin IR in the product information, cholinergic stimulants, such as the acetylcholinesterase inhibitors, involve the mutual antagonism of anticholinergic agents and extended-release.

In another study that pooled results of two open-label studies, tolterodine LA was associated with significantly greater patient-perceived improvement in bladder control and fewer withdrawals due to adverse effects than oxybutynin XL. However, the treatments were similar in terms of patients’ or physicians’ perception of benefit over baseline and proportions of withdrawals due to lack of efficacy. However, the lack of blinding may have introduced patient and observer bias.

Oxybutynin XL, available only in a tablet formulation, is administered once daily, with or without food, and should not be crushed or chewed (see Table 94–4). Like oxybutynin IR, the dosage does not require adjustment in patients of advanced age or in patients with renal or hepatic impairment. However, treatment should be initiated at the smallest recommended dosage in the elderly (5 mg once daily). The maximum benefit of oxybutynin XL may not be realized for up to 4 weeks after starting therapy or after dose escalation. No known clinically relevant drug–drug interactions with either oxybutynin XL or oxybutynin IR have been identified. However, other drugs with anticholinergic activity may increase overall anticholinergic effects (i.e., produce an additive or synergistic pharmacodynamic interaction), as might be expected. Another potential pharmacodynamic interaction involves the mutual antagonism of anticholinergic agents and cholinergic stimulants, such as the acetylcholinesterase inhibitors used to treat dementia.

### Extended-Release Transdermal Oxybutynin

The oxybutynin transdermal system (TDS), which delivers 3.9 mg/day, is applied twice weekly (every 3 or 4 days). Transdermal absorption of oxybutynin from this formulation bypasses first-pass hepatic and gut metabolism, resulting in similar plasma oxybutynin but lower plasma DEO concentrations compared with levels achieved after administration of an equivalent dose via the oral route. No dosage adjustment of the TDS product for advancing age is necessary.

Oxybutynin TDS is superior to placebo in reducing the number of incontinence episodes and micturations and increasing the volume voided per micturition. It is similar to oxybutynin IR in reducing the frequency of UUI episodes and improving patient-perceived urinary leakage. Oxybutynin TDS and tolterodine LA are significantly superior to placebo and similar to each other in reducing the frequency of UUI episodes, increasing the volume voided per micturition, attaining complete continence, and improving quality of life.

### Immediate-Release Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist that can be considered first-line therapy for UI in patients with symptoms of urinary frequency, urgency, or urge incontinence.

Controlled studies demonstrated that tolterodine was significantly more effective than placebo and as effective as oxybutynin IR in decreasing the mean daily number of micturations and increasing the mean volume voided per micturition. Although three controlled trials showed a significant decrease in the mean number of incontinence episodes per 24 hours compared with placebo, most other studies have not confirmed the finding, and the manufacturer’s package insert does not claim a significant improvement in this parameter. The only controlled study of the ability of tolterodine to restore urinary continence reported an insignificant effect size of 9% over placebo.

### Extended-Release Tolterodine

In a controlled study of 1,529 adult outpatients with urinary frequency and UUI, tolterodine LA, an extended-release formulation of tolterodine, significantly...
decreased the mean number of weekly incontinence episodes (23% effect size over placebo and 7% effect size over tolterodine IR). Premature study withdrawal rates did not differ significantly between the two active treatments, but dry mouth was observed significantly less often in patients taking the LA formulation than among those receiving the IR formulation.\(^4\)

Tolterodine LA was significantly superior to placebo and similar in elderly and young patient populations in reducing the frequencies of incontinence episodes and micturitions, increasing the volume voided per micturition and ability to complete tasks before voiding, and enhancing patient perception of benefit. Adverse effect types and frequencies were similar in the two age groups.\(^7\)

A major consideration in using tolterodine is its pharmacokinetics, specifically its metabolism. The agent is predominantly eliminated by hepatic metabolism, which is partially under the control of genetic polymorphism.\(^3\) The principal metabolic pathway in extensive metabolizers involves oxidation of the parent drug by CYP isoenzyme 2D6 to the active 5-hydroxymethyl metabolite (DD01), followed by further oxidation and dealkylation. In poor metabolizers who lack the CYP 2D6 (approximately 7% of the U.S. population), the principal metabolic pathway involves CYP 3A4, with dealkylation of the amino group, oxidation to a dealkylated hydroxy metabolite, and further oxidation to a dealkylated acid metabolite that undergoes glucuronidation. Because tolterodine is principally metabolized by CYP 3A4 in this case, its elimination may be impaired by inhibitors of this isoenzyme (e.g., fluoxetine, sertraline, fluvoxamine, macrolide antibiotics, azole antifungals, and grapefruit juice). For example, fluoxetine, an inhibitor of CYP 2D6 and 3A4, decreases the metabolism of tolterodine to DD01. The result is a mean 4.8-fold increase in the tolterodine area under the plasma concentration–time curve (AUC), mean 52% decrease in peak plasma concentration, and mean 20% decrease in the AUC of DD01.\(^\) Whether tolterodine significantly alters the pharmacokinetics of drugs metabolized by CYP 2D6 is unknown, so caution is advised with concurrent use with agents metabolized by CYP 2D6.

Single-dose interaction studies have demonstrated that concurrent administration of tolterodine LA with antacid leads to rapid release of drug (70% within 4 hours) and a mean 1.5-fold elevation in tolterodine peak plasma concentration compared with placebo. The same studies showed that the pharmacokinetics of oxybutynin XL were unaltered by concurrent antacid administration.\(^7\)

Another single-dose study showed that concurrent administration of tolterodine LA with omeprazole 20 mg once daily resulted in significantly increased peak plasma tolterodine concentrations compared with tolterodine LA given without prior omeprazole use. Conversely, no significant differences in peak plasma concentrations of oxybutynin were evident when the XL formulation was administered with or without omeprazole. However, the AUCs of both agents were not significantly affected by omeprazole administration.\(^7\) The clinical implication of this interaction is unclear. Whether a similar interaction exists with histamine H\(_2\)-receptor antagonists is unknown.

One of two phase I pharmacokinetic studies comparing tolterodine pharmacokinetics in healthy elderly volunteers (age 64–80 years) with those in healthy volunteers younger than 40 years found no significant differences in pharmacokinetic parameters between the groups. However, in the second phase I study, the mean serum concentrations of tolterodine and DD01 were 20% and 50% greater in elderly volunteers than in young healthy volunteers, respectively. Despite possibly altered pharmacokinetics in elderly individuals, no differences in the incidences and severity of adverse events between these age groups have been noted in clinical trials, so no dosage adjustment is recommended on the basis of age alone.\(^7\)

Tolterodine elimination is diminished in patients with impaired hepatic function. Patients with hepatic cirrhosis who are extensive metabolizers exhibit a significantly higher mean AUC of DD01, higher serum tolterodine and DD01 concentrations, and longer terminal disposition half-life of tolterodine and DD01 than do healthy subjects who are extensive metabolizers. The tolterodine AUC is higher in cirrhotic patients who are poor metabolizers than in healthy people who are poor metabolizers.\(^3\) If use of tolterodine cannot be avoided in patients with hepatic impairment or in those receiving inhibitors of CYP 3A4 (and possibly inhibitors of CYP 2D6), the initial dose should be reduced by 50% to tolterodine IR 1 mg twice daily or tolterodine LA 2 mg once daily.\(^7\) No formal tolterodine dosage recommendation is possible based on available information for individuals who concurrently have hepatic impairment and are taking a CYP 3A4 and/or 2D6 inhibitor. Intuitively, the initial dose should not exceed 1 mg twice daily (IR) or 2 mg once daily (LA).

Elimination of tolterodine has not been evaluated in patients with impaired renal function; therefore, the drug should be used more cautiously in such individuals (i.e., starting dose of IR product is 1 mg twice daily with gradual dose escalation, if needed, to the usual maximum of 2 mg twice daily or a starting dose of the LA formulation is 2 mg once daily with gradual dose escalation, if needed, to the usual maximum of 4 mg once daily).\(^7\)

Tolterodine is better tolerated than oxybutynin IR, with approximately 8% of patients discontinuing treatment prematurely (compared with approximately 27% of individuals taking oxybutynin IR).\(^3,5,2,3,6,9,41,42,6,7,9\) The most common adverse effects of tolterodine are dry mouth, dyspepsia, headache, constipation, and dry eyes.\(^7\)

Tolterodine, available only as a tablet formulation, can be taken with or without food. The LA product should not be crushed or chewed or taken less than 2 hours before or 4 hours after antacid administration. The maximum benefit from tolterodine may not be realized for up to 8 weeks after starting therapy or dose escalation.

**Fesoterodine Fumarate** Fesoterodine fumarate is a prodrug that is metabolized to the active metabolite, 5-hydroxymethyl tolterodine, by nonspecific plasma esterases. It is an alternative first-line therapy for UI in patients with symptoms of urinary frequency, urgency, or urge incontinence.\(^6\) While both hepatic metabolism and renal excretion contribute to the elimination of the active metabolite, no dosage adjustment is necessary in patients with mild to moderate renal or hepatic impairment. The usual starting dose is 4 mg daily, increasing to 8 mg daily, as needed and tolerated. The dose of fesoterodine should not exceed 4 mg daily in the presence of severe renal impairment (creatinine clearance <30 mL/min [0.50 mL/s]) or in patients also taking potent CYP3A4 inhibitors. Fesoterodine has not been studied and is not recommended in patients with severe hepatic impairment.\(^6,9,10\)

Placebo-controlled studies have demonstrated that fesoterodine 4 and 8 mg daily reduces the number of micturitions/day and the frequencies of incontinence episodes and urgency episodes per week, and the drug increases the number of continent days/week and volumevoided/micturition. It also improves quality-of-life compared with placebo. Response is dose-related, with greater responses occurring with the 8 mg versus the 4 mg daily dose (exception: micturition frequency). In the only active comparator trial, fesoterodine 4 and 8 mg and tolterodine LA 4 mg (all given once daily) were all significantly superior to placebo in the majority of efficacy parameters. Fesoterodine and tolterodine were not compared statistically in the trial.

In a post hoc comparison, fesoterodine 8 mg daily was superior to tolterodine LA 4 mg daily in several efficacy parameters. Caution is warranted in interpreting the results of post hoc analyses, however.

The most common adverse effects of fesoterodine are dry mouth (27%), constipation (5.1%), dyspepsia (2%), and dry eyes (1.6%).\(^6\) The most common adverse effects in the active comparator trial were dry mouth (3.8%, 21.7%, 16.9%); constipation (3.3%, 4.5%, 8.5%); and dyspepsia (2%, 2%, 2%).
2.8%); and dry eyes (2.2%, 4.2%, <1%) in the fesoterodine 4 and 8 mg and tolterodine LA 4 mg recipients, respectively. 80,81

At this time, fesoterodine does not appear to be a significant advance on existing anticholinergics in managing UUI.

**Trospium Chloride** Trospium chloride is a quaternary ammonium anticholinergic. It was approved in 2004 by the U.S. Food and Drug Administration (FDA) for the management of overactive bladder but has been available for many years in other countries. Trospium chloride has been comprehensively reviewed. 82 The data discussed here derive from that review, supplemented with detailed clinical trial data.

Preclinical studies have demonstrated that trospium chloride is an antimuscarinic agent in bladder and gastrointestinal tract tissues. It is poorly absorbed after oral administration (<10%), and food reduces bioavailability by 70% to 80%. It is principally cleared by the renal route (70%), with 80% of urinary excretion accounted for by the parent compound. The mean terminal disposition half-life in the presence of normal renal function is 10 to 12 hours. Advancing age and mild to moderate hepatic impairment do not affect trospium chloride pharmacokinetics to a clinically significant degree. In contrast, renal impairment does significantly reduce drug clearance. When creatinine clearance is less than 30 mL/min (0.50 mL/s), AUC is increased by a mean of 4.5-fold, peak plasma concentration by a mean of twofold, and terminal disposition half-life by a mean of two- to threefold.

Eleven published English-language studies on the efficacy/tolerability of trospium chloride for treatment of UUI are available. Except for the two trials (one published) described in the product information, clinical trials have emphasized cystometric, not clinical, endpoints. 85-92

The paucity of clinical outcome data makes difficult the evaluation of trospium chloride compared with other approved anticholinergics. Although trospium chloride is statistically superior to placebo, the absolute differences in results between trospium chloride and placebo call into question the clinical relevance of such differences. In the four trials with active controls, results with trospium chloride and an active control are available. The effect sizes (solifenacin effect minus placebo effect) in these studies are similar to those noted with oxybutynin.

The expected anticholinergic adverse effects occur with trospium chloride as well. Of interest, the frequency of these events is increased in patients 75 years and older compared with younger subjects. This occurrence is believed to be pharmacodynamic (i.e., increased sensitivity) and not pharmacokinetic in nature. No data at present support the hypothesis that trospium chloride is less neurotoxic than nonquaternary ammonium anticholinergics. Solifenacin succinate is believed to be a "uroselective" agent. The drug is well absorbed (mean absolute bioavailability, 88%), and food has no clinically relevant effect on absorption. 98,99 It is principally cleared by the renal route (70%), with 80% of urinary excretion accounted for by the positive electrical charge on the quaternary nitrogen. Available drug–drug interaction data are clearly inadequate.

The usual dosage regimen is 20 mg twice daily. The drug should be taken on an empty stomach. Dosage reduction (by 50% of the daily dose) is recommended when creatinine clearance is less than 30 mL/min (0.50 mL/s). In patients 75 years and older, dose reduction to 20 mg once daily should be considered based upon tolerability. At this time, trospium chloride does not appear to be a significant advance over oxybutynin and tolterodine in managing UUI.

**Extended-Release Trospium Chloride** Like the immediate-release formulation, extended-release trospium chloride 60 mg daily is an alternative first-line therapy for treatment of overactive bladder with symptoms of UI, urgency, and urinary frequency. 93

Because food decreases the bioavailability by 35% to 60%, extended-release trospium chloride must be taken on an empty stomach (1 hour before or 2 hours after meals). 93-94 Trospium is eliminated primarily unchanged in the urine. The pharmacokinetics of this version of trospium chloride in patients with mild to moderate renal impairment have not been studied, and it is not recommended in patients with severe renal impairment (creatinine clearance <30 mL/min [0.50 mL/s]). 95

Extended-release trospium chloride was evaluated in two 12-week, randomized, controlled studies. In a Phase III study, extended-release trospium chloride 60 mg daily (n = 298) improved urinary frequency, urgency, and UI more than placebo did (n = 303). 93

In another phase III study, extended-release trospium chloride 60 mg daily (n = 267) improved the number of voids per day, number of days with UI episodes per day, number of days with no UI episodes, urgency severity, volume voided per micturition, and overactive bladder (OAB) Symptom Composite Score compared with placebo (n = 276). 96 There are no studies comparing extended-release trospium chloride with an active control.

The most common adverse effects with extended-release trospium chloride have been dry mouth (11%), constipation (9%), dizziness (2%), dry eyes (1.6%), flatulence (1.6%), nausea (1.4%), and abdominal pain (1.4%). 93

At this time, extended-release trospium chloride does not appear to be a significant advance on trospium chloride or other existing anticholinergics in managing UUI.

**Solifenacin Succinate** Solifenacin succinate was approved by the FDA in late 2004 for treatment of overactive bladder with urge incontinence, urgency, and urinary frequency. Solifenacin succinate has been comprehensively reviewed. 97 The data discussed here derive from that review, supplemented with detailed clinical trial data.

Preclinical studies demonstrated that solifenacin is an antagonist at M1, M2, and M3 muscarinic cholinergic receptors. Based on comparative ex vivo and animal studies with solifenacin and oxybutynin, solifenacin is believed to be a "uroselective" agent. The drug is well absorbed (mean absolute bioavailability, 88%), and food has no clinically relevant effect on absorption. 98,99 It is principally eliminated via metabolism and renal excretion of metabolites, with renal excretion of parent compound less than 10% of the dose. With a mean terminal disposition half-life of 50 to 60 hours, the drug can be dosed once daily. 100 Results of two placebo-controlled and two placebo- and active (tolterodine)-controlled clinical trials in UUI are available. Like oxybutynin and tolterodine, solifenacin significantly reduced the number of incontinence episodes, urge episodes, and micturitions per day and increased the volume voided per micturition in a dose-dependent fashion compared with placebo. In the active-controlled trials, solifenacin was statistically superior to tolterodine. However, neither of these two studies directly compared solifenacin and tolterodine. 101,102 Surprisingly, the effect of tolterodine in these trials was no better than that of placebo. A direct comparative trial of tolterodine ER demonstrated that the effect of solifenacin was significantly greater than that of tolterodine ER in terms of reducing the number of UI episodes and pad usage and in improving patients’ perception of their bladder condition. 103 An analysis of pooled data from two phase III studies showed that solifenacin recipients had significant improvement in five of 10 quality of life domains from baseline compared with placebo recipients. 104

No comparative efficacy/tolerability data with oxybutynin are available. The effect sizes (solifenacin effect minus placebo effect) in these studies were similar to those noted with oxybutynin.
A retrospective analysis of pooled data from elders (mean age 72 years) in four phase III studies showed that compared with baseline, solifenacin recipients achieved a significantly greater decrease in number of UUI episodes, number of urgency episodes, and number of micturitions per day and a greater increase in the proportion of patients who became totally dry compared with placebo recipients.105 The recommended dose of solifenacin is 5 mg once daily. If the drug is well tolerated but the effectiveness is not optimal, the dose can be increased to 10 mg once daily. Little additional benefit is generally achieved with doses exceeding 5 mg daily. Solifenacin can be administered with or without food. For patients with creatinine clearance rates less than 30 mL/min (0.50 mL/s) or with moderate hepatic impairment (Child-Pugh class B), the daily dosage should not exceed 5 mg. If the patient has severe hepatic impairment (Child-Pugh class C), the drug should not be used. If the patient is receiving concurrent therapy with one or more potent CYP 3A4 inhibitors, the daily dose should not exceed 5 mg. In contrast to findings of preclinical studies, solifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, blurred vision, and other anticholinergic effects to a similar extent as tolterodine in clinical trials and oxybutynin in pharmacokinetic trials. At this time, solifenacin does not appear to be a significant advance over existing anticholinergics in managing UUI.

Darifenacin The data on darifenacin discussed here derive from a review,106 supplemented with detailed clinical trial data. Preclinical studies have demonstrated that darifenacin is an antagonist at M1, M3, and M4 muscarinic cholinergic receptors. As with solifenacin, darifenacin is believed to be “uroselective” on the basis of preclinical data. The mean absolute bioavailabilities of the 7.5-, 15-, and 30-mg extended-release (ER) formulations are 15%, 19%, and 25%, respectively. Bioavailability is affected by formulation, CYP 2D6 genotype, dose, and race. Bioavailability is enhanced using an ER formulation (70%–110% higher than IR), in heterozygous CYP 2D6 extensive metabolizers and poor metabolizers (40%–90% higher than homozygous extensive metabolizers), and white race (56% higher than Japanese). Darifenacin is extensively metabolized, with cumulative urinary excretion of the parent compound less than 10%. The 2D6 and 3A4 isoenzymes of CYP are responsible for darifenacin metabolism. With a mean terminal disposition half-life of 3 to 5 hours (depending on CYP 2D6 metabolizer status), an ER formulation is needed to allow once-daily dosing. Results of four placebo-controlled clinical trials (one published) on UUI are available. Although a comparative study of darifenacin with oxybutynin IR showed that both agents significantly decreased the number of UUI episodes and their severity as well as urinary urgency and the number of micturitions compared with placebo, the active treatments were not directly compared.107 A comparison with tolterodine IR and placebo showed that darifenacin 15 mg and 30 mg significantly decreased the number of UUI episodes from baseline after 2 weeks compared with placebo, but only the 30-mg daily dose continued to be superior to placebo after 12 weeks. Compared with placebo, tolterodine IR did not significantly decrease the number of UUI episodes from baseline at either time point. Darifenacin 30 mg once daily achieved a significantly greater decrease in the number of UUI episodes compared with tolterodine IR at both time points. At 12 weeks, both darifenacin and tolterodine IR produced significant improvements from baseline in the number of micturitions per day and volume voided per micturition compared with placebo.108 A large pooled subanalysis of patients 65 years and older from three phase III studies demonstrated that darifenacin produced a significant decrease in the number of UUI episodes, urgency episodes, and micturition frequency and an increase in volume voided per micturition compared with placebo.109 No comparative efficacy/tolerability data with anticholinergics other than tolterodine IR and oxybutynin IR are available.

The recommended daily dose of darifenacin is 7.5 to 15 mg once daily of the ER oral formulation. As with solifenacin, darifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, and other well-known anticholinergic adverse effects. Dry mouth was significantly more common with oxybutynin IR than either darifenacin or placebo.110 In one study, the rates of treatment discontinuation and adverse events in elderly recipients of darifenacin were similar to those seen in other studies of darifenacin conducted in younger adults.105 At this time, darifenacin does not appear to be a significant advance over existing anticholinergics in managing UUI.

Other Anticholinergics and Antispasmodics Other drugs for treatment of UUI are less effective, are no safer, or have not been adequately studied.28,111 Thus their use is not recommended. Tricyclic antidepressants are generally no more effective than oxybutynin IR, and they exhibit a high incidence of bothersome and potentially serious adverse effects (e.g., orthostatic hypotension, cardiac conduction abnormalities, dizziness, and confusion). They are also potentially life threatening in overdose. Therefore, their use should be limited to individuals who have one or more additional medical indications for these agents (e.g., depression or neuropathic pain); patients with mixed UI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly those with nocturnal incontinence associated with altered sleep patterns.28,111–114 Because of the lower incidence of adverse effects, desipramine and nortriptyline may be preferred over imipramine and doxepin. However, due to their lower anticholinergic activity, they may not be as effective.

Should anticholinergic pharmacotherapy be used to treat UUI in patients with mild cognitive impairment or mild or moderate dementia?

Which anticholinergic agent should be used as first-line pharmacotherapy of UUI (oxybutynin, tolterodine, trospium chloride, solifenacin, darifenacin, or fesoterodine) and which formulation of oxybutynin (oral IR, oral XL, TDS patch, or topical gel) or tolterodine (oral IR, oral LA) is unclear. Financial considerations currently favor generic oxybutynin IR, and this is the initial choice of many clinicians. Due to differences between agents in terms of adverse event rates, patient comorbidities may favor the use of more expensive branded agents.

Propantheline, a quaternary ammonium anticholinergic and potential treatment, produces a high incidence of adverse effects and is only modestly effective for UUI.115–117 When used, propantheline appears to be best tolerated at a dose no more than 15 mg three times daily plus 60 mg at bedtime.116

Flavoxate is a tertiary amine that relaxes smooth muscle in vitro. Four controlled trials revealed that flavoxate is no more effective than placebo for treatment of UUI; therefore, flavoxate is not recommended.28
Dicyclomine hydrochloride, an anticholinergic agent that relaxes smooth muscle, produced minimal benefit as well as bothersome adverse effects in two small studies.\textsuperscript{120,121} Hyoscyamine, an anticholinergic and antispasmodic drug related to atropine, has been suggested for treatment of UUUI, but data recommending its use are insufficient.\textsuperscript{28}

In a meta-analysis, 50 randomized, controlled trials and three pooled analyses were examined for significant (with $P < 0.05$) and nonsignificant (NS) differences. Adverse events were seen less frequently with use of LA products, as compared with IR formulations (oxybutynin: incidences of any AE, xerostomia, and moderate–severe or severe xerostomia; tolterodine: incidence of xerostomia). Of interest, the incidence of headache was higher with the use of LA versus IR formulations of tolterodine. The efficacy of LA tolterodine compared with the IR formulation favored the LA formulation for the parameters of number of micturitions and volume voided per micturition. However, the number of incontinence episodes and pad use were similar for the two formulations.\textsuperscript{122}

For tolterodine IR, efficacy was similar for the 2 mg and 4 mg daily doses, while only xerostomia occurred more frequently with the 4 mg daily dose. With solifenacin, the only efficacy parameter different for the 5 mg and 10 mg daily doses was the percentage of patients with a 50% or greater reduction in incontinence episode frequency (10 mg > 5 mg). The 10 mg daily dose of solifenacin was associated with higher frequencies of study withdrawal due to adverse events, xerostomia, and constipation than was the 5 mg daily dose. For darifenacin, the 15 mg daily dose, as compared with the 7.5 mg daily dose, was associated with higher frequencies of study withdrawal due to adverse events, xerostomia, and constipation. Also, the 30 mg daily dose, as compared with the 15 mg daily dose, was associated with higher frequencies of xerostomia and constipation.\textsuperscript{122}

For comparisons between drugs, only for oxybutynin versus tolterodine were the data adequate for meta-analysis. The IR products were similar in efficacy. Oxybutynin IR was associated with higher frequencies of any adverse event, study withdrawal due to adverse events, xerostomia, and constipation than was tolterodine LA. Oxybutynin IR was also associated with higher frequencies of xerostomia and severe xerostomia than was tolterodine LA.\textsuperscript{122}

Lastly, oral oxybutynin IR/tolterodine LA, as compared with the oxybutynin TDS (patch) formulation, produced similar reductions in the number of incontinence episodes. However, the oral agents were associated with higher frequencies of xerostomia and constipation, compared with the TDS (patch) formulation. In contrast, the TDS (patch) formulation was associated with higher frequencies of local (application site) reactions and study withdrawal due to adverse effects, compared with the oral agents.\textsuperscript{122} The analysis predated the availability of the oxybutynin topical gel formulation.

In summary, the following can be concluded on the basis of available data. LA formulations are generally preferable over IR ones in terms of improved tolerability. Dose escalation of IR formulations may result in improved efficacy, albeit limited, at the cost of an increase in adverse event frequency/severity. The TDS (patch) route does not provide significant advantages over the oral route. No conclusion can be made currently with regard to the topical gel route.

Table 94–5 lists the adverse event frequencies for the most common events for oxybutynin, tolterodine, trospium chloride, solifenacin, darifenacin, and fesoterodine based on manufacturers’ product information.

**Botulinum Toxin A** Enthusiasm is considerable for the application of botulinum toxin A for treatment of voiding dysfunction. Botulinum toxin is a naturally occurring powerful muscle relaxant produced by *Clostridium botulinum*. Injected into smooth or striated muscle, botulinum toxin acts as a neurotoxin by temporarily paralyzing the muscle. The mechanism of action of the paralytic effect is generally ascribed to prevention of the release of the neurotransmitter acetylcholine into the synapse at the neuromuscular junction, although other pathways in neuromodulation may also be affected.

This compound is commercially produced for medical use in a number of conditions such as muscle spasticity, hyperhidrosis, and cosmetic reduction of skin wrinkles. It does not carry an FDA-approved indication in any lower urinary tract disorders, although many studies are ongoing. In the urinary tract, it can be used to treat overactive bladder (detrusor) muscle as well as external urethral sphincter spasticity. Botulinum toxin has been used successfully and safely in patients with neurogenic bladder dysfunction and nonneurogenic detrusor overactivity and overactive bladder.\textsuperscript{123–125}

Botulinum toxin is delivered using a cystoscope equipped with a needle. The usual dosage is between 100 and 300 units per session. It is injected through the needle directly into the bladder muscle in 10 to 30 injections spaced over 5 to 10 minutes. The procedure is carried out as an outpatient procedure without general anesthesia. The duration of therapeutic effect varies, lasting usually from 4 to 8 months. Repeat injections are necessary to maintain the beneficial effects.

The adverse effects of botulinum toxin A when used in the urinary tract most frequently include dysuria, hematuria, urinary tract infection, and urinary retention. Urinary retention occurs in up to 20% of treated individuals and persists until the paralytic effects have worn off (up to 6 to 8 months). Therapeutic and adverse effects may not become evident for 3 to 7 days, presumably because this period of time is required for uptake of the toxin following injection.

Results of an open-label trial of intravesical botulinum toxin A in dimethylsulfoxide in 21 women with refractory idiopathic detrusor overactivity demonstrated a significant reduction in the frequency of incontinence episodes without any effect on postvoid residual urine volumes.\textsuperscript{126} Much work remains to determine whether the intravesical (i.e., instillation into the bladder) route for botulinum toxin A administration is feasible for the treatment of OAB.

**Catheterization Combined with Medications** Patients with UUUI and an elevated postvoid residual urine volume due to retention may require intermittent self-catheterization along with frequent voiding between catheterizations.

If intermittent catheterization is not possible, surgical placement of a suprapubic catheter may be necessary. Use of a chronic indwelling catheter should be avoided because of the increased occurrence of urinary tract infections and nephrolithiasis.

Regardless of catheterization status, patients may experience symptom relief with oxybutynin (IR, XL, or TDS formulations), tolterodine (IR or LA formulations), trospium chloride, solifenacin, fesoterodine, or darifenacin, as these agents relax the detrusor muscle and enhance bladder storage. Patients with UUUI and symptoms of retention may also benefit from an $\alpha$-adrenergic receptor antagonist that relaxes the internal bladder sphincter (e.g., prazosin, terazosin, doxazosin, tamsulosin, silodosin, and alfuzosin). Although theoretically of benefit, bethanechol, a cholinergic agonist, has not been demonstrated effective in improving bladder emptying in well-done trials. In addition, it causes numerous bothersome (e.g., muscle and abdominal cramping and diarrhea) and potentially life-threatening adverse effects and should not be used in patients with asthma or heart disease.\textsuperscript{29}

**Urethral Underactivity** Urethral underactivity, or SUI, may be aggravated by agents with $\alpha$-adrenergic receptor blocking activity, including prazosin, terazosin, doxazosin, tamsulosin, alfuzosin, silodosin, methyldopa,
clonidine, guanfacine, guanadrel, and labetalol. The goal of therapy is to improve the urethral closure mechanism by stimulating α-adrenergic receptors in the smooth muscle of the bladder neck and proximal urethra, enhancing the supportive structures underlying the urethral epithelium, or enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex. There is no role for medications in the management of SUI after radical prostatectomy.

**Estrogens** Local and systemic estrogens have been used extensively for the pharmacologic management of SUI since the 1940s. Estrogens are believed to work via several mechanisms, including enhancement of the proliferation of urethral epithelium, local circulation, and numbers and/or sensitivity of urogenital α-adrenergic receptors. However, a trial has questioned whether estrogens exert a stimulatory effect on vaginal collagen production, at least over the short term.

Open trials support the use of a variety of estrogens in the management of SUI: transdermal estradiol, conjugated estrogen vaginal cream, Estrin, oral conjugated estrogen, oral quinestradol, oral estriol, intramuscular estrogens, estriol vaginal suppositories, and oral estradiol. Variable effects of estrogen treatment on urodynamic parameters, such as maximum urethral closure pressure, functional urethral length, and pressure transmission ratio, have been noted in these studies. Progestogens have an antagonistic effect compared with estrogens, by reducing genitourinary tract muscle tone.

Results of four placebo-controlled comparative trials have not been as favorable, finding no significant clinical or urodynamic effects for oral estrogen compared with placebo. In fact, observational studies have documented that estrogen use is associated with an increased risk of UI compared with that in nonusers. Systemic estrogen therapy is associated with numerous adverse effects, including mastodynia, uterine bleeding, nausea, thromboembolism, cardiac and cerebrovascular ischemic events, and enhancement of the risk of certain cancers. If estrogens are to be used for treatment of SUI, only topical products should be administered. Estrogen use is best justified when SUI exists with urethritis or vaginitis due to estrogen deficiency.

**α-Adrenergic Receptor Agonists** Numerous open trials have supported the use of a variety of α-adrenergic receptor agonists in SUI, including ephedrine, norfenzefrine, phenylpropanolamine, and midodrine. Phenylpropanolamine was withdrawn from the U.S. market in 2000 because of a risk for stroke in women using the agent. Some patients may have leftover supplies of this agent or may obtain it from international sources. If so, individuals with the concomitant conditions listed later in the chapter (especially coronary artery disease and/or cardiac arrhythmias) should be warned against self-treatment with this or other α-adrenergic receptor agonists.

Placebo-controlled comparative trials with phenylpropanolamine, norfenzefrine, and norephedrine support the modest efficacy of these agents for treatment of mild or moderate SUI. These agents have been found to variably affect maximum urethral closure pressure and functional urethral length.

Adverse effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness. Contraindications to the use of these agents include the presence of hypertension, tachyarrhythmias, coronary artery disease, myocardial infarction, cor pulmonale, hyperthyroidism, renal failure, and narrow-angle glaucoma.

Usual doses for pseudoephedrine and phenylephrine are listed in Table 94–4.

Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α-adrenergic receptor agonist exceed those of the individual therapies in SUI. In general, combination therapy has resulted in somewhat superior clinical and urodynamic responses compared with monotherapy, including severity of complaints, amount of urine lost per episode, number of daily voluntary micturitions, number of leakage episodes per day, patient preference, pad use, maximum urethral closure pressure, functional urethral length, and pressure transmission ratio.

**Duloxetine** Duloxetine, a dual inhibitor of serotonin and norepinephrine reuptake, was approved in 2004 for treatment of depression and pain associated with diabetic neuropathy. Its use for treatment of SUI (for which the drug is approved in many countries but not in the United States) is based on studies in rats and cats demonstrating that central serotoninergic and noradrenergic regions are involved in ascending and descending control of urethral smooth muscle and the external urethral sphincter. These mechanisms facilitate the bladder-to-sympathetic reflex pathway, increasing urethral and external urethral sphincter muscle tone during the storage phase. Data documenting this control mechanism in humans are limited. The mean terminal disposition half-life, clearance, and volume of distribution of duloxetine in healthy volunteers are 10 to 12 hours, 114 to 119 L/h, and 1,787 to 1,943 L, respectively. The drug is extensively metabolized to inactive metabolites (via oxidation at the 4, 5, and/or 6 positions in the naphthyl ring, followed by further oxidation or via methylation) with elimination in the urine as conjugated metabolites. CYP 2D6 and 1A2 are involved in the ring oxidations. This involvement was demonstrated in studies of the interaction of duloxetine with the CYP 2D6 substrate desipramine (wherein desipramine’s peak plasma concentration, AUC, and terminal disposition half-life were increased 1.7-, 2.9-, and 1.9-fold, respectively, and clearance fell by 66%) and the CYP 2D6 inhibitor paroxetine (wherein duloxetine’s peak plasma concentration, AUC, and terminal disposition half-life increased 1.6-, 1.6-, and 1.3-fold, respectively, and clearance fell by 37%). Fluvoxamine, a CYP 1A2 inhibitor, increased duloxetine’s peak plasma concentration, AUC, and terminal disposition half-life by over 5-fold, 2.5-fold, and 3-fold, respectively. Thus clinicians must be careful when prescribing duloxetine concurrently with CYP 2D6 and 1A2 substrates or inhibitors. The effect of advancing age on duloxetine pharmacokinetics is not clinically significant. Moderate hepatic dysfunction (Child-Pugh class B) significantly affects duloxetine disposition, increasing mean AUC and terminal disposition half-life by 5-fold and 3-fold, respectively, and reducing clearance 85% compared with controls. Mild or moderate renal impairment (creatinine clearance 30–80 mL/min [0.50–1.34 mL/s]) does not affect drug disposition. In severe renal impairment (hemodialysis patients), peak plasma concentration and AUC are increased 100%, whereas metabolite concentrations are increased up to 900%.

Results of six large clinical trials with duloxetine in SUI have been published. All were double-blinded, randomized, placebo-controlled, and parallel group in design. Compared with placebo, duloxetine therapy produced significant reductions in incontinence episode frequency and number of micturitions per day, improvement in Incontinence quality of life questionnaire scores and patient self-assessment, and increase in mean micturition interval. Results were independent of baseline UI severity (severity based on incontinence episode frequency). Significant intergroup differences were seen by week 4. However, cure rates were generally not improved by duloxetine. When evaluating the absolute differences between treatments, the actual benefit of duloxetine was generally quite modest.

A randomized, placebo-controlled clinical trial evaluated the effects of duloxetine (80 mg daily), pelvic floor muscle training (PFMT), and the combination of both modalities on incontinent episode frequency, incontinence-related quality of life, pad use, and patient global impression of change. Sham PFMT was used in the placebo group. Results indicated that duloxetine plus PFMT were probably additive in effect and that combination therapy afforded greater improvement than either monotherapy.
Although duloxetine is an encouraging development in the pharmacologic management of SUI, its adverse event profile may make adherence problematic. In the SUI trials, treatment-emergent adverse events occurred in 68% to 93% of duloxetine and 50% to 72% of placebo recipients. Premature study withdrawal rates (due to adverse events) were 12% to 33% for duloxetine and 2% to 8% for placebo. The frequencies of individual events in duloxetine recipients were nausea 9% to 16%, headache 7% to 14%, constipation 4% to 27%, dry mouth 4% to 22%, dizziness 8% to 16%, fatigue 10% to 18%, somnolence 8% to 13%, vomiting 6% to 13%, and diarrhea 4% to 6% of interest, the drug may be associated with small increases in blood pressure (like venlafaxine, another dual reuptake inhibitor) and withdrawal symptoms (sleep disturbances). Unfortunately, adherence to long-term therapy is quite poor due to a combination of adverse events and lack of efficacy.  

Despite these negatives, duloxetine is the first drug approved by a regulatory agency for treating SUI. Based on studies conducted to date, a dosage regimen of 40 to 80 mg/day (in one or two doses) appears reasonable. Initiating therapy with 40 mg daily for 2 weeks and then increasing to 80 mg daily (rather than initiating therapy with 80 mg daily) reduces the risks of nausea, dizziness, and premature drug discontinuation. If the drug is to be stopped, it should be withdrawn slowly, reducing the dose by 50% for 2 weeks before discontinuation, unless the situation is potentially life-threatening.  

A double-blind, randomized, placebo-controlled clinical trial has recently demonstrated the benefit of venlafaxine 75 mg once daily for 12 weeks over placebo in terms of incontinence episode frequency, voiding interval, quality of life, and patient global improvement.  

## Overflow Incontinence  
Overflow incontinence secondary to benign or malignant prostatic hyperplasia may be amenable to pharmacotherapy. For management of malignant prostatic disease, see Chapter 139. The pharmacotherapy of BPH is discussed in Chapter 93.  

### CLINICAL CONTROVERSY  
The optimal approach to pharmacotherapy of SUI is unclear. Although not supported by evidence-based medicine, many clinicians initiate a trial of topical estrogen, followed by addition of an α-adrenergic receptor agonist in estrogen nonresponders unless contraindicated. Based on available data, duloxetine is the drug of choice for treatment of SUI, provided it is tolerated.  

### SURGICAL TREATMENT  
Only rarely does surgery play a role in the initial management of UI. In the absence of secondary complications from UI (e.g., skin breakdown or infection), the decision to surgically treat symptomatic UI should be based on the premise that the degree of bother or lifestyle compromise to the patient is great enough to warrant an elective operation, and that nonoperative therapy either is undesired or has been ineffective.  

Successful application of surgery depends most on defining the underlying abnormalities responsible for UI (bladder vs urethra, underactivity vs overactivity). Once the underlying factors are determined, other considerations include renal function, sexual function, severity of leakage, history of abdominal or pelvic surgery, presence of concurrent abdominal or pelvic pathology requiring surgical correction, and finally the patient’s suitability for, and willingness to accept the risks of, surgery.  

When patients with uncomplicated SUI become dissatisfied with the initial management approaches of pelvic floor exercises, medications, and/or behavioral modification, surgical treatment assumes the primary role.  

Surgical correction of female SUI (urethral underactivity) is directed toward either (a) repositioning the urethra and/or creating a backboard of support, or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic (intraabdominal) position that is receptive to changes in intraabdominal pressure; or (b) improving the sealing mechanism and/or creating compression or otherwise augmenting the urethral resistance provided by the intrinsic sphincteric unit, with (i.e., sling) or without (i.e., periurethral collagen and other injectables) urethral and bladder neck support. Midurethral synthetic slings have become the most common approach to the treatment of SUI in women in the United States. These can be inserted in outpatient procedures that have shorter convalescence periods and allow faster return to usual activities compared with many of the older procedures.  

As noted previously, SUI in men is very rare in the absence of prior pelvic surgery, injury, or neurologic disease. In men, SUI can be treated in a number of ways. Collage or other bulking agents can be injected perirethraly and submucosally into the region of the external urinary sphincter. The goal of these injections is to improve the sealing effect of the poorly functioning sphincter mechanism. The vast majority of perirethral bulking injections in men are performed in a retrograde fashion under direct visualization through a cystoscope. This approach is less effective and far less durable than alternative surgical procedures, although it can be performed in the office setting without the need for general anesthesia. The artificial urinary sphincter is generally considered to be the gold standard for treatment of male SUI. Placement of the manually operated silicone device has been associated with very high long-term success and satisfaction rates. Male slings placed through a perineal incision are a newer alternative to the artificial urinary sphincter. However, long-term efficacy and safety data are lacking.  

Most patients with UUI are managed nonsurgically with a combination of behavioral modification, pelvic floor exercises, and pharmacologic therapy. Only rarely is surgery applied to the problem of UUI. Surgery for the treatment of UUI generally consists of implantation of a sacral nerve stimulator (neuromodulation) or augmentation (enlargement) cystoplasty. Posterior tibial nerve stimulation is a new office-based percutaneous treatment for UUI or OAB. Long-term efficacy and safety data are lacking. Additional information and a systematic review of these procedures are available.  

Few surgical treatments for bladder underactivity are effective. After an appropriate evaluation for reversible causes is performed, the most effective management of this condition is intermittent self-catheterization performed by the patient or a caregiver three or four times per day.Sacral nerve stimulation (neuromodulation) has shown some efficacy in this patient population, but success rates for detrusor underactivity (nonobstructive urinary retention) are inferior to those seen with urinary frequency and urgency. Proper patient selection for this therapy remains poorly defined. Alternative methods of management that are less satisfactory or more invasive include indwelling urethral or suprapubic catheters and urinary diversion.  

Urethral overactivity is most commonly caused by anatomic obstruction. Anatomic obstruction in men is most often caused by benign prostatic enlargement (see Chap. 93).  

Rarely, bladder outlet obstruction is caused by a functional obstruction at the level of the bladder neck. Hypertrophy of the smooth muscle fibers at the level of the bladder neck in men and women may result in obstruction to the flow of urine. In patients who do not respond to pharmacologic therapy with α-adrenergic receptor antagonists, endoscopic incision using the cystoscope is highly effective in treating this very uncommon condition.
EVALUATION OF THERAPEUTIC OUTCOMES

During long-term management of UI, patient-specific clinical signs and symptoms of most distress (“bother”) to the individual must be monitored. A daily diary may be useful in this regard. Some of the short-form instruments used in incontinence research for measuring symptom impact and condition-specific quality of life can be used in clinical monitoring. In addition, quantitating the use of ancillary supplies, such as pads, may be useful. The goal of therapy is to minimize the signs and symptoms most bothersome to the patient, as well as the use of pads and other ancillary supplies or devices. Total elimination of UI signs and symptoms may not be possible, and patients and practitioners need to mutually establish realistic goals of therapy. Because the therapies for UI frequently have nuisance adverse effects (e.g., anticholinergic effects such as xerostomia, xerophthalmia, and constipation) that may compromise regimen adherence, the presence and severity of adverse effects must be carefully elicited at each visit to the healthcare practitioner. Emergence of adverse effects may necessitate drug dosage adjustment or use of alternative strategies (e.g., chewing sugarless gum, sucking on hard sugarless candy, or use of saliva substitutes in xerostomia) or even drug discontinuation.

ABBREVIATIONS

AUC: area under the plasma or serum concentration-versus-time curve
BPH: benign prostatic hyperplasia
CYP: cytochrome P450
DDO1: 5-hydroxymethyl metabolite of tolterodine
DEO: N-desethyloxybutynin
ER: extended release
IR: immediate release
LA: long acting
NS: nonsignificant
OAB: overactive bladder
PFMT: pelvic floor muscle training
SUI: stress urinary incontinence
TDS: transdermal system
UI: urinary incontinence
UUI: urge urinary incontinence
XL: extended release

REFERENCES

An understanding of the mechanism by which immunomodulators act along with an understanding of the immune system allows a clinician to anticipate potential adverse effects. The benefit of manipulating the immune responses must be balanced with the potential consequences and long-term sequela of such manipulation.

The immune system is a complex network of barriers, organs, cellular elements, and molecules that interact to defend the body against invading pathogens. Actually, the immune system is composed of two distinct systems of immunity: innate immunity and adaptive immunity. In brief, innate immunity includes a series of nonspecific barriers (physical and chemical), along with cellular and molecular elements strategically predeployed and prepositioned to prevent and/or quickly neutralize infection. Working in concert with innate immunity is adaptive immunity. In contrast to innate immunity, adaptive immunity constantly evolves and adapts against invading pathogens. Its hallmarks include diversity, memory, mobility, self vs non-self discrimination, redundancy, replication, and specificity. Diversity indicates the capability of the immune system to respond to many different pathogens or strains of pathogens. Immunological memory ensures a quicker and more vigorous response to a subsequent encounter with the same pathogen. Mobility of components of the immune system enables local reactions to provide systemic protection. Discrimination of self vs non-self helps prevent friendly-fire damage of the host by the immune system. Redundancy refers to the immune system’s ability to produce components with similar biological effects from multiple cells lines, such as inflammatory cytokines. Replication of the cellular components of the immune system amplifies the immune response. Specificity describes the ability of the immune system to distinguish between dissimilar antigens.

**MAJOR TISSUES AND ORGS OF THE IMMUNE SYSTEM**

While numerous cells of the immune system have the ability to migrate to most body tissues, some tissues and organs serve as key members of the immune system. These include primary and secondary lymphoid tissues and organs. Primary lymphoid tissues...
and organs provide an environment appropriate for the development and maturation of select cells of the immune system. It is here that these select cells of the immune system mature and become tolerant of self and competent to respond to foreign antigens. Secondary lymphoid organs provide an environment where various cells of the immune system interact with and respond to trapped foreign antigens.  

**BONE MARROW**

Bone marrow is the predominant primary lymphoid tissue of the body because it is the source of all cellular elements of the blood (erythrocytes, leukocytes, and thrombocytes [i.e., platelets]). The few exceptions to this rule are mostly confined to fetal development when some blood cells are transiently produced in the yolk sac, liver, spleen, thymus, and lymph nodes. Regardless of where they are formed, all blood cells arise from common self-renewing pluripotent stem cells via the process of hematopoiesis (Fig. 95–1). During hematopoiesis, pluripotent stem cells differentiate along particular myeloid and lymphoid lineages to produce the leukocytes of the immune system, erythrocytes, and thrombocytes. Hematopoiesis is controlled by soluble mediators called hematopoietic growth factors/cytokines or colony stimulating factors (CSFs) that are multifunctional and drive responses such as growth, survival, proliferation, differentiation, maturation, and functional activation. The destiny of the leukocytes (if they survive the maturation process) is to become mature cells of the immune system directly from the bone marrow (all leukocytes except T lymphocytes), or to migrate out of the bone marrow to continue their maturation elsewhere (T lymphocytes). Selected hematopoietic growth factors are identified in Figure 95–1, and a more comprehensive list appears in Table 95–1. Currently, four human hematopoietic cytokines have one or more recombinant products that are FDA-approved for clinical use: erythropoietin (EPO); granulocyte colony-stimulating factor (G-CSF); granulocyte-macrophage colony-stimulating factor (GM-CSF); and interleukin 11 (IL-11).  

**THYMUS**

The thymus is a bi-lobed primary lymphoid organ located in the superior mediastinum between the aorta and the sternum. Its primary function is to produce mature T cells (thymus-dependent organs) provide an environment appropriate for the development and maturation of select cells of the immune system. It is here that these select cells of the immune system mature and become tolerant of self and competent to respond to foreign antigens. Secondary lymphoid organs provide an environment where various cells of the immune system interact with and respond to trapped foreign antigens.

**FIGURE 95-1.** Basic model of hematopoiesis, outlining the various pathways blood cells take from their origin as bone marrow stem cells through stages in which they are progressively selected to become monopotent mature cells with specific functions. Selected hematopoietic growth factors include: EPO, erythropoietin; FLT-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.

lymphocytes), which are the leukocytes responsible for cell-mediated immunity, including cytotoxic actions and immunoregulation. Through an intricate multistep process called thymic education, T cells that respond appropriately and are beneficial to the immune system mature and leave the thymus. T cells that fail the thymic education test (99%) are eliminated via apoptosis.

SPLEEN

The spleen is a slender elongated secondary lymphoid organ located in the upper left quadrant of the abdomen that receives blood from the splenic artery. Although it is not a vital organ, it functions as an immunological filter of the blood and destroys defective and old erythrocytes. It contains compartments designated as red pulp and white pulp and provides an environment for the interaction of its filtered debris from blood with antigen-presenting cells and lymphocytes responsible for cell-mediated responses (T cells) and lymphocytes responsible for antibody production (B cells). Red pulp serves as a site of red blood cell degradation, and the white pulp provides an environment for the interaction of B cells and T cells. The spleen sequesters many cellular elements (leukocytes, erythrocytes, and platelets) and can become dangerously congested in a condition termed splenomegaly.

LYMPH NODES

Lymph nodes are normally small BB-sized lymphoid organs widely distributed between the groin and the neck. While the spleen filters blood, lymph nodes act as immunological filters for interstitial lymphatic fluid from the body’s tissues. Lymph nodes provide an environment for the interaction of filtered debris with antigen-presenting cells and other immune cells (T cells and B cells). Lymph nodes may sequester activated immune cells (or tumor cells) and become inflamed and engorged causing lymphadenopathy.

MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)

Mucosa-associated lymphoid tissue (MALT) is the most extensive component of human lymphoid tissue and is distributed along mucosal linings of the body. MALT may consist of well-defined networks of primary lymphoid follicles and other associated immunocompetent cells (adenoids, appendix, intestinal Payer’s patches, and tonsils), small solitary lymph nodes, or loosely organized clusters of lymphoid cells that are found in intestinal villi. The primary function of these tissues is to filter, trap, and remove pathogens that breach mucosal surfaces. In addition to neutralizing pathogens, MALT generates plasma cells (activated B cells) that secrete IgA antibodies.

As mentioned earlier, the immune system includes two functional divisions: (1) the innate or nonspecific which encodes evolutionary genes aimed at providing rapid responses against nonmammalian targets and (2) the adaptive or specific which utilizes cells which can genetically rearrange their DNA to create specific structures which bind individual antigens or proteins (Table 95–2). Despite this simple separation, these divisions extensively interact. Awareness of each component of the immune system and the consequences of disrupting homeostasis must be understood in order to appropriately dose, administer, and monitor the effect of medications given to manipulate immune responses.

METHODS TO DISTINGUISH SELF FROM NON-SELF

The immune system is designed to attack and destroy a broad spectrum of foreign antigens/pathogens. The immune system must however be able to distinguish self from non-self, termed self-tolerance, in order to avoid unleashing its components onto self-tissues. The body employs many tactics to avoid attacking itself, and when self-tolerance fails this may lead to the development of an autoimmune disease.

INNATE IMMUNE SYSTEM

Physical Defense

Physical and chemical defenses are the most rudimentary form of innate immunity and the first line of defense against invading pathogens. The skin, the largest organ of the body, has the primary role of providing a physical defense. Alterations in the skin, such as burns or abrasions, allow an easy portal of entry for pathogens. The gastrointestinal tract also provides physical defense. The low pH of the stomach (pH 1–2) is inhospitable to most organisms. The rapid
turnover of intestinal cells also limits systemic infection as cells including infected cells are sloughed frequently. Drugs, such as cell-cycle, phase-specific antineoplastics that disrupt the sloughing process, leave the patient at an increased risk for infections. Likewise, the respiratory tract has its forms of physical defense. The mucus coating the epithelial cells serves in part to prevent microorganisms from adhering to cell surfaces, and the cilia lining the epithelium of the lungs help to repel inhaled organisms. The combination of cilia, mucus, and reactive coughing provides a natural barrier to invasion via the respiratory tract. Other examples of mechanical or nonspecific defenses include normal urine flow, lysozymes in tears and saliva, and the normal flora in the throat, the lower gastrointestinal tract, and the genitourinary tract. Disruption of the normal physical defense system through mechanical ventilation, for example, places the host at substantial risk for penetration by a pathogenic organism. 12

**Innate Immune Response**

If an infectious pathogen invades and is able to infiltrate through a host’s physical defense system, innate immunity is employed to halt progression of the infection. Innate immunity is present from birth and utilizes a preexisting but limited repertoire of receptors to recognize and destroy pathogens. Innate immune cells include subgroups of leukocytes; specifically, monocytes/macrophages, neutrophils, basophils, mast cells, and eosinophils. When stimulated by a foreign pathogen, mast cells and basophils secrete inflammatory mediators. Monocytes/macrophages, neutrophils, mast cells, and eosinophils act as phagocytes, which allow them to recognize, internalize, and destroy invading pathogens. This process may occur in two ways: opsonin-dependent or opsonin-independent phagocytosis. For opsonin-dependent phagocytosis, antibody (e.g., IgG), complement (e.g., C3b), or lectin (e.g., C-reactive protein) coat, or opsonize, the infectious pathogens. Once the pathogen is opsonized, the antibody, complement, or lectin binds to the receptors on the phagocyte (Fig. 95–2) and activates the phagocytic process. For opsonin-independent phagocytosis, innate leukocytes utilize pattern recognition receptors. Pattern recognition receptors recognize highly conserved structures present on a large number of microorganisms. These highly conserved structures are essential for the microorganism’s survival or pathogenicity. The pattern recognition receptors include the macrophage mannose receptor, macrophage scavenger receptor, and members of the toll-like receptor family. Pattern recognition receptors on the phagocytes directly recognize ligands (Table 95–3) on the surfaces of infectious pathogens leading to immediate phagocytosis of the pathogen (Fig. 95–2). Toll-like receptors are a family of pattern recognition receptors on the cell-surface of innate leukocytes. To date, 11 toll-like receptors have been identified in humans. They recognize a broad spectrum of antigens ranging from lipopolysaccharide and flagellin on bacteria to zymosan on yeast to double-stranded RNA from RNA viruses (Table 95–3). Binding of the ligand to the toll-like receptors allows the phagocyte to recognize and engulf the pathogen. This binding of toll-like receptors to its ligand also results in the secretion of chemokines, inflammatory cytokines, and antimicrobial peptides as well as the increased expression of co-stimulatory proteins (e.g., B7) and the major histocompatibility complex proteins by the phagocyte. This leads to the recruitment and activation of antigen-specific lymphocytes. 10,13,14 Other pattern recognition receptors that mediate phagocytosis include MARCO (macrophage receptor with collagenous structure), DC-SIGN (Dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin), and dectin 1.

**Cells of the Innate Immune System**

Neutrophils, eosinophils, and basophils are considered granulocytes because of the presence of numerous cytoplasmic granules in these cells that contain inflammatory mediators or digestive enzymes. Their names are derived from their staining characteristics; neutrophils are named because they stain a neutral pink. Neutrophils comprise the majority of leukocytes in the bloodstream. They are polymorphonuclear cells, often denoted as PMNs for this reason, which serve as the primary human defense against invasive bacteria. Neutrophils migrate from the bloodstream into infected or inflamed tissue in response to chemotactic factors, such as IL-8 and C3a and C5a, breakdown products of complement. In this migration, a process termed chemotaxis, neutrophils reach the site of inflammation and then recognize, adhere to, and phagocytose pathogens. Via the complement and antibody receptors located on its surface, neutrophils can recognize and engulf pathogens opsonized with complement or IgG (antibody). During phagocytosis, the engulfed pathogen is internalized within the phagocyte into a cytoplasmic lysosome. The neutrophil then releases its granular contents into lysosome and generates the release of oxidative metabolites that destroy the engulfed pathogens. 15 Neutrophils can also recognize pathogens via toll-like receptors.

Eosinophils are also granulocytic cells involved in innate immunity. They exhibit motility and migrate from the blood into the tissues. They play a less significant role in combating bacterial infections, but eosinophils play a major role against nonphagocytizable multicellular

![Figure 95-2](image-url)
pathogens, such as parasites. After activation via high-affinity receptor for IgE (i.e., Fce), eosinophils exocytose their granules causing the release of basic proteins or reactive oxygen species into the microenvironment, causing lysis of the parasite. In addition to Fce receptors, eosinophils express lower levels of complement receptor 3 and Fcv for IgG than neutrophils. The high affinity of eosinophils for IgE contribute to their role in the pathogenesis of allergic disorders (i.e., allergic asthma).16

Macrophages and monocytes are mononuclear cells capable of phagocytosis. Tissue macrophages arise from the migration of monocytes from the bloodstream into the tissues. Macrophages differ from monocytes by possessing an increased number of Fc and complement receptors. Macrophages are found within specific tissues such as the liver, spleen, gastrointestinal tract, lymph nodes, brain, and others. These specific types of macrophages are often called histiocytes, or referred to by a specialized name depending on the site where they are found (for example, Kupffer cells in the liver, osteoclasts in the bone, microglial cells in the central nervous system). The term reticuloendothelial system (RES) was commonly used to refer to macrophages found in reticular connective tissue, but the preferred nomenclature is now the mononuclear phagocyte system.27

Despite the first description in 1868 of Langerhans cells, a type of dendritic cell found in the skin, our current understanding of the biologic function of dendritic cells did not develop until the past decade. Before pathogen recognition, most dendritic cells are in an immature/resting state with limited ability to activate T lymphocytes, but they express numerous receptors (e.g., Fc receptors of IgG and IgE, macrophage mannose receptor, toll-like receptors) enabling rapid antigen recognition. Following antigen recognition and particle engulfment, dendritic cells become activated. This leads to a dramatic increase in their expression of the major histocompatibility complex (MHC) class II, CD40, and adhesion molecules. Dendritic cells then begin to migrate through the tissues towards lymphoid organs (e.g., spleen, lymph nodes) to present antigen to T lymphocytes, causing activation of the adaptive immune system.18

In addition to phagocytosing pathogens, macrophages and dendritic cells act as antigen-presenting cells (APCs) to stimulate the adaptive (specific) system. Macrophages and dendritic cells internalize the organism, digest it into small peptide fragments, and then combine these antigenic fragments together with MHC proteins. Once the APC has formed the antigen/MHC complex, the APC places the complex on its surface. This surface complex can then be recognized by the T-cell receptor on the surface of a T lymphocyte. The recognition of the antigen/MHC complex by the T-cell receptor is the first step in the activation of the T lymphocyte (Fig. 95–3). Other cells, B lymphocytes and mast cells, can also act as APCs (Fig. 95–4).18–19

Mast cells and basophils act primarily by releasing inflammatory mediators. Mast cells are tissue cells predominately associated with IgE-mediated inflammation. They are especially abundant in the skin, lungs, nasal mucosa, and connective tissue. Granules within the mast cells contain large amounts of preformed mediators that include histamine, heparin, and serotonin. Mast cells can also phagocyte, destroy, and present bacterial antigens to T lymphocytes.18 Basophils are similar to mast cells because they contain granules filled with histamine, but they are typically found circulating in the blood and are not found in connective tissue. Like mast cells, basophils also express high-affinity IgE Fc receptors (Fce). IgE-mediated anaphylaxis (type I hypersensitivity; Chap. 97) is caused by the stimulation of mast cell and/or basophil degranulation and the release of preformed mediators after allergen binds to IgE bound to the Fce receptor on the surface of mast cells or basophils.19

**Soluble Mediators of the Innate Immune System**

Soluble mediators of innate immunity include the complement system, mannose-binding lectin, antimicrobial peptides, and C-reactive protein (CRP). The complement system consists of more than 30 proteins in the plasma and on cell surfaces that play a key role in immune defense. The four major functions of the complement system include (1) to lyse certain microorganisms and cells, (2) to stimulate the chemotaxis of phagocytic cells, (3) to coat or opsonize foreign pathogens which allows phagocytosis of the pathogen by leukocytes expressing complement receptors, and (4) to clear immune complexes. Complement factors (C3a, C5a) act as chemotactic factors for phagocytic cells.20 Two different pathways stimulate the complement cascade. In the classic pathway, antibody binds to its target antigen and activates the first component of complement (C1), thereby initiating the complement cascade. The alternative complement pathway relies on the inability of microorganisms to clear spontaneously produced C3b, the active form of third complement protein, from their surface. Patients with hereditary deficiencies of complement have recurrent bacterial infections or immune complex disease because C3b plays a central role in opsonizing bacteria and clearing immune complexes. Both mannann-binding lectin and C-reactive protein are acute-phase reactants produced by the liver during the early stages of an infection. They bind to infectious pathogens that prompt the activation of the lectin or minor pathway of the complement system. Mannann-binding lectin binds to mannose-rich glycoconjugates on microorganisms while C-reactive protein binds to phosphorylcholine on bacterial surfaces.8,20

**Chemokines** play an essential role in linking the innate and adaptive immune response by orchestrating leukocyte trafficking. The chemokine system consists of a group of small polypeptides and their receptors. Chemokines possess four conserved cysteines. Based on the positions of the cysteines, almost all chemokines
B lymphocytes become memory B lymphocytes. In the presence of these cytokines plus antigen binding to the sIg, the B lymphocyte becomes activated. The activated B lymphocyte becomes a plasma cell (4), which produces and secretes immunoglobulin or becomes a memory B lymphocyte (5). A minority of B lymphocytes become memory B lymphocytes.

The body will generally employ both the innate and adaptive immune responses to rapidly kill foreign pathogens. The greatest difference between the innate and adaptive immune responses is in specificity and memory, characterized by antigen-specific receptors located on the surface of B and T lymphocytes. The adaptive immune response also secretes cytokines to further amplify the innate immune response. The adaptive immune response can evolve with each subsequent infection whereas the innate response stays the same with each infection. During B- and T-lymphocyte development, an individual B or T lymphocyte rearranges its immunoglobulin and T-cell receptor genes, respectively, to produce a unique immunoglobulin or T-cell receptor, respectively. This DNA rearrangement generates enough B or T lymphocytes to recognize an estimated $10^{15}$ antigens.

The adaptive immune response can be divided into two major arms: humoral and cellular mediated. The humoral response is so denoted because it was discovered that the factors that provided the immune protection could be found in the “humor” or serum. B lymphocytes comprise the humoral arm. Activated B lymphocytes can differentiate into plasma cells that secrete immunoglobulin or memory B cells specific for each pathogen. T lymphocytes constitute the cell-mediated arm of the adaptive system. The immune protection provided by T lymphocytes cannot be transferred by serum alone. Rather, it is essential to actually have T lymphocytes present, thus the term cell-mediated immunity. T lymphocytes are specially tailored to defend against infections that are intracellular, such as viral infections, whereas the antigen-loaded dendritic cell leaving the tissue and migrating toward the lymph nodes.

Naturally occurring antimicrobial peptides include α-defensins, β-defensins, and cathelicidins. These peptides exhibit antibacterial, antifungal, and antiviral activity. Human antimicrobial peptides range in size from 29 to 37 amino acid residues in length. Neutrophils are rich source of both α- and β-defensins as well as cathelicidins. Other sources of the human antimicrobial peptides include keratinocytes, paneth cells of the intestinal and genital tracts, and epithelial cells of the pancreas and the kidney. These peptides can be induced at sites of inflammation or can be constitutively produced. The clinical interest in human antimicrobial peptides centers on their broad spectrum activity and their rapid onset of killing. They are believed to work by disrupting microbial membranes. An active area of research is how these peptides discriminate between microbial and host membranes.

### ADAPTIVE IMMUNE SYSTEM

#### Adaptive Immune Response: Antigen Recognition

The body will generally employ both the innate and adaptive immune responses to rapidly kill foreign pathogens. The greatest difference between the innate and adaptive immune responses is in specificity and memory, characterized by antigen-specific receptors located on the surface of B and T lymphocytes. The adaptive immune response also secretes cytokines to further amplify the innate immune response. The adaptive immune response can evolve with each subsequent infection whereas the innate response stays the same with each infection. During B- and T-lymphocyte development, an individual B or T lymphocyte rearranges its immunoglobulin and T-cell receptor genes, respectively, to produce a unique immunoglobulin or T-cell receptor, respectively. This DNA rearrangement generates enough B or T lymphocytes to recognize an estimated $10^{15}$ antigens.

The adaptive immune response can be divided into two major arms: humoral and cellular mediated. The humoral response is so denoted because it was discovered that the factors that provided the immune protection could be found in the “humor” or serum. B lymphocytes comprise the humoral arm. Activated B lymphocytes can differentiate into plasma cells that secrete immunoglobulin or memory B cells specific for each pathogen. T lymphocytes constitute the cell-mediated arm of the adaptive system. The immune protection provided by T lymphocytes cannot be transferred by serum alone. Rather, it is essential to actually have T lymphocytes present, thus the term cell-mediated immunity. T lymphocytes are specially tailored to defend against infections that are intracellular, such as viral infections, whereas

B lymphocytes secrete antibodies that can neutralize pathogens prior to their entry into host cells.

**Adaptive Immune Response: Cells Which Mediate Antigen Recognition**

The role of the T lymphocyte is to search and destroy pathogens that infect and replicate intracellularly. When these pathogens enter a cell they are no longer vulnerable to innate host defenses; therefore, it is critical that the T lymphocytes be able to distinguish which cells are infected and which cells are not. T lymphocytes do not recognize intact antigens, such as a bacterial cell wall. T lymphocytes only recognize processed antigens in association with MHC.

The major histocompatibility complex, a cluster of genes found on chromosome 6 in humans, is also known as the human leukocyte antigen (HLA) complex. The MHC is used by the immune system to distinguish self from non-self and provides a so-called immunologic “fingerprint.” The genes from this complex encode for molecules that play a pivotal role in immune recognition and response. The MHC complex is divided into three different classes: I, II, and III. The molecules encoded by class I HLA genes include HLA-A, HLA-B, and HLA-C antigens. These molecules can be found on all nucleated cells within the body, as well as on platelets. Class I antigens are not found on mature red blood cells. Molecules encoded by class II HLA genes include HLA-DP, HLA-DQ, and HLA-DR. The expression of these molecules is more restricted and can be found primarily on cells of the immune system, namely antigen-presenting cells such as macrophages, dendritic cells, and B lymphocytes. The class III HLA antigens encode for soluble factors, complement, and tumor necrosis factors. In order for a CD4+ T lymphocyte to become activated, CD4+ T lymphocyte must recognize the antigenic peptide in association with MHC class II (Figs. 95–3 and 95–4). CD8+ T lymphocytes recognize antigenic peptide in association with class I molecules. Class I molecules generally contain endogenous peptides from within the cell, such as those derived from viruses, whereas class II molecules contain exogenous peptides from the antigen that has been phagocytosed and digested, such as bacterial peptides (Fig. 95–3). For it to destroy a virally infected cell, a CD8+ cytotoxic T lymphocyte requires two steps. First, its T-cell receptor must recognize the antigenic fragment, such as a viral protein, in association with MHC class I. The second step involves the co-stimulatory step of B7-1 (CD80) and B7-2 (CD86) binding. This process is further defined below. Because any cell can become infected, it is advantageous that the CD8+ cytotoxic T lymphocytes recognize the MHC class I molecule that is expressed on all cells except red blood cells. The ability of the MHC class I to present endogenous peptides allows the CD8+ cytotoxic T lymphocytes to constantly screen cells for infections. Dendritic cells and macrophages demonstrate the unique capacity to direct exogenous antigens toward MHC class I molecules, a process termed cross-presentation. APCs (e.g., macrophages, dendritic cells) engulf the pathogen, digest it, and express its peptide fragments on their cell surface in association with their MHC. T lymphocytes use a specific antigen receptor, T-cell receptor (TCR), to propagate the immune response. The TCR is comprised of two chains with each chain having a variable and a constant region. The variation of the amino acid sequence within the variable domain of TCR gives the cell its unique antigen specificity. Linked to the TCR is a complex of single chains known as the CD3 complex.

Naïve T lymphocytes, are cells that have not been previously exposed to an antigen specific for their TCR. These cells require two signals for activation. The first signal for activation involves the T lymphocyte recognizing both the processed antigen and the MHC molecule complex. The second signal involves the interaction of the B7-1 (CD80) or B7-2 (CD86) molecule on the APC with the CD28 molecule on the surface of the T lymphocyte (Figs. 95–3 and 95–4). Without the second signal, the naïve T lymphocyte becomes anergic or inactive. Memory T lymphocytes are less dependent on the second signal than are naïve T lymphocytes. CD28 is expressed on both resting and activated T lymphocytes while CTLA-4, a second ligand for B7 on T lymphocytes, is expressed only on activated T lymphocytes. CTLA-4 binding B7 transduces a negative signal so it plays a role in downregulating a T-lymphocyte response. After the two activation signals, a message is sent through the TCR to the CD3 complex into the cell. Then a calcium influx occurs with subsequent activation of the T lymphocyte. Activated CD4+ T lymphocytes begin to express the high-affinity IL-2 receptor and to release multiple soluble factors (e.g., IL-2) to stimulate T lymphocytes and other cells of the immune system (Fig. 95–3). Autocrine stimulation by IL-2 leads to the proliferation of the activated T lymphocyte.

Cell surface markers delineate the functional activity of T-lymphocyte populations. All T lymphocytes express the CD3 protein. Typically, T lymphocytes are further divided into helper cells (CD4+), suppressor cells (CD8+), and cytotoxic cells (CD8+). Each of the subclasses appears to play a distinct role in the cell-mediated immune response. Naïve T lymphocytes express CD45RA, a high-molecular-weight isoform of CD45, while memory T lymphocytes express CD45RO, a lower-molecular-weight isoform of CD45. The primary role of CD4+ cells is to stimulate other cells in the immune response. Functionally, CD4+ cells can be divided into TH1 and TH2. This functional system was first described in mice. TH1 cells secrete IL-2 and γ-interferon and stimulate CD8+ cytotoxic cells, whereas TH2 cells secrete IL-4, IL-5, and IL-10 and stimulate B-lymphocyte production of antibody. Multiple factors determine whether a naïve CD4+ T lymphocyte develops into a TH1, or a TH2, cell. The cytokine microenvironment plays an important role in this development. IL-12 secreted by the APCs promotes TH1, whereas IL-4 promotes TH2 development. Other factors that promote TH1 development include B7-1 (CD80), high-affinity for the TCR for the antigen, γ-interferon, and α-interferon. Factors that promote TH2 development include B7-2 (CD86), low-affinity for the TCR for the antigen, IL-10, and IL-1.

CD8+ T lymphocytes recognize antigen in association with MHC class I. CD8+ cytotoxic cells are instrumental in killing cells recognized as foreign, such as those that have become infected by a virus. CD8+ cytotoxic T lymphocytes also play an important beneficial role in the eradication of tumor cells, but moreover are responsible for rejection of transplanted organs. Classically, a second type of CD8+ T lymphocytes was a suppressor cell. It is clear that some T lymphocytes help suppress the immune response, but whether this subset is CD8+ is debatable. Emerging evidence is leading away from CD8+ T lymphocytes toward CD4+, CD25+ T lymphocytes in maintaining self-tolerance. The preferred term for these suppressive T lymphocytes is regulatory T lymphocytes.

To fully activate the CD8+ cytotoxic T lymphocyte requires CD4+ T lymphocyte activation, namely the TH1 subset, and its subsequent secretion of IL-2 (Fig. 95–5a). This model of CD8+ cytotoxic T lymphocyte activation requires the close proximity of two-antigen specific T lymphocytes. In addition, some CD8+ cytotoxic T-lymphocyte responses can occur in the absence of CD4+ T lymphocytes. New data suggests that CD4+ T-lymphocytes can activate/prime APCs through CD40. This interaction primes the APC (e.g., dendritic cell) to fully activate CD8+ cytotoxic T lymphocytes (Fig. 95–5b). It is important to remember that the classification of CD4+ lymphocytes as T-helper lymphocytes and CD8+ lymphocytes as T-cytotoxic lymphocytes is not an
the target cell membrane. Besides a direct cytotoxic effect on the target cell, the pores produced by perforins allow the granzymes to penetrate into the target cell to induce apoptosis. The second mechanism of cytotoxicity involves the binding of Fas ligand on the cytotoxic T lymphocyte to the Fas receptor on the target cell. The Fas ligand is predominately expressed on CD8+ cytotoxic T lymphocytes and NK cells, and its expression increases after activation. After destroying that target cell by either mechanism, the cytotoxic T lymphocyte detaches from the target cell and attacks other targets. 32

A B lymphocyte recognizes antigen via its antibody or immunoglobulin located on its cell surface (Fig. 95–4). The antibody on the surface can recognize an intact pathogen, such as bacteria, and present antigen to T lymphocytes (i.e., acting as APC). However, the major function of B lymphocytes is to produce antibody to bind to the invading pathogen, a process that first entails activation of the B lymphocyte. The activation of B lymphocytes also requires two steps: (1) recognition of antigen by the surface immunoglobulin and (2) the presence of B-lymphocyte growth factors (IL-4, -5, -6) secreted by activated CD4+ T lymphocytes. Once activated, the B lymphocyte becomes a plasma cell, a differentiated cell capable of producing and secreting antibody. A fraction of activated B lymphocytes do not differentiate into plasma cells, but rather form a pool of memory cells. The memory cells will respond to subsequent encounters with the pathogen, generating a quicker and more vigorous response to the pathogen. Some B lymphocytes can become activated without help from T lymphocytes, but these responses are generally weak and do not invoke memory. 9,15

Natural killer (NK) cells, often referred to as large granular lymphocytes, are defined functionally by their ability to lyse target cells without prior sensitization and without restriction by MHC. Resting NK cells express the intermediate-affinity IL-2 receptor, CD122. Upon exposure to IL-2, NK cells exhibit greater cytotoxic activity against a wide variety of tumors. NK cells recognize target cells by two mechanisms. First, NK cells express an IgG Fc receptor, CD16 that allows recognition of IgG-coated cells. Second, NK cells express killer-activating and killer-inhibiting receptors. The killer-activating receptors recognize multiple targets on normal cells; however, the binding of MHC class I to the killer-inhibitor receptor blocks release of perforins and granzymes. Therefore, cells (e.g., tumor cells, virally infected cells) that downregulate MHC class I expression are susceptible to NK cell cytolysis. NK cells play important roles in the surveillance and the destruction of tumors and virally infected host cells, and in the regulation of hematopoiesis. 9,33

**Soluble Mediators of the Adaptive Immune Response**

When binding of a specific antigen to the surface immunoglobulin receptor of B lymphocytes occurs, the B lymphocyte matures into a plasma cell and produces large quantities of antibody that have the ability to bind to the inciting antigen. The secreted antibodies may be of five different isotypes. On primary exposure to the pathogen, the plasma cell will secrete IgM; then, eventually, there is a switch to predominately IgG. On secondary exposure, the memory B lymphocytes will predominately produce IgG. Isotype switching from IgM to IgG, IgA, or IgE is controlled by T lymphocytes.

An antibody or immunoglobulin is a glycoprotein comprised of two different chains, heavy and light (Fig. 95–6). The basic structure of every immunoglobulin consists of four peptide chains: two identical heavy chains and two identical light chains held together by disulfide bonds. The basic structure of the antibody is a Y-shaped figure. Each arm of the Y is formed by the linkage of

**FIGURE 95-5.** In the classic model of CD8+ T-lymphocyte activation (A), CD4+ and CD8+ T lymphocytes recognize antigen on the same dendritic cell. In the presence of interleukin (IL)-2 from the activated CD4+ T lymphocyte and the recognition of antigen in association with major histocompatibility complex (MHC) class I, the CD8+ T lymphocyte becomes activated. In the new model (B), activated CD4+ T lymphocytes activate dendritic cells via CD40 ligand binding to CD40. The activated dendritic cell then migrates through the tissues to present antigen to CD8+ T lymphocytes. If recognition via the T-cell receptor (TCR) on the CD8+ T lymphocyte occurs, the dendritic cell can fully activate the CD8+ T lymphocyte without the presence of CD4+ T lymphocytes.

absolute. Some CD8+ T lymphocytes secrete cytokines similar to a T-helper lymphocyte, and some CD4+ T lymphocytes can act as cytotoxic cells.

Unlike neutrophils and macrophages, cytotoxic T lymphocytes are unable to ingest their targets. They destroy target cells by two different mechanisms: the perforin system and the Fas ligand pathway. After recognition by the cytotoxic T lymphocyte, cytoplasmic granules containing perforins and granzymes are rapidly oriented toward the target cell, and the contents of the granules are released into the intracellular space. Like the membrane attack complex formed after complement activation, perforins form a pore in

FIGURE 95–6. Schematic diagram of the structure of the immunoglobulin G (IgG) molecule. IgG molecule consists of two heavy (H) and two light (L) chains covalently linked by disulfide bonds. Each chain is composed of variable (V) and constant (C) regions. A light chain consists of one variable (V_L) and one constant (C_L) region. Heavy chains consist of one variable (V_H) and three or four constant (C_H) regions, depending on the isotype. The variable regions (V_L and V_H) compose the antigen-binding region of the IgG molecule, or fragment antigen binding (Fab). The constant regions provide the structure to the IgG molecule as well as binding the first component of complement (C1) and binding to Fc receptors via the Fc portion of the molecule (C2, C3).

the end of the light chain to its heavy chain partner. These arms contain the portions described as the fragments of antigen binding (Fab fragments). The stem of the Y contains the heavy chains which make up the fragment crystallizable (Fc fragment) portion of the antibody. It is within the Fc portion that complement is activated once the antibody has bound its target. Likewise, it is the Fc portion of the antibody that is recognized by Fc receptors on the surface of phagocytes (Fig. 95–2). The amino acid composition of the same isotype is homogenous except in the variable regions of the light (V_L) and heavy chains (V_H). The variation in amino acid composition of the variable region gives the antibody its unique specificity (Fig. 95–6).

IgG, the most prevalent of the antibody classes, comprises approximately 80% of serum antibody. IgG is usually the second isotype of antibody to be produced in an initial humoral immune response. IgG is the only isotype of antibody that can cross the placenta. Therefore, early maternal humoral protection of neonates is primarily due to maternal IgG that crossed the placenta in utero.

Four different subclasses of IgG have been described: IgG1, IgG2, IgG3, and IgG4. These subclasses differ slightly in their constant amino acid sequences. IgG1 constitutes the majority (60%) of the subclasses. It appears that different subclasses recognize different types of antigen. IgG1 and IgG3 are principally responsible for recognition of protein antigens while IgG2 and IgG4 commonly bind to carbohydrate antigens. Another difference in the subclasses is the ability to activate complement with IgG3 and IgG1 being the most efficient, but IgG4 is unable to activate the complement system.

IgM can be found on the surface of B lymphocytes as a monomeric Y-shaped structure. In contrast, secreted IgM is a pentamer in which five of the monomers are joined together by a joining chain (J-chain). IgM is the first class of antibody to be produced on initial exposure to an antigen. Because the pentameric form of IgM has no Fc portions exposed, phagocytic cells cannot bind pathogens opsonized by IgM. However, IgM is an excellent activator of the complement cascade by the classic pathway.

IgA is found primarily in the fluid secretions of the body: tears, saliva, nasal fluids; and also in the gastrointestinal, genitourinary, and respiratory tracts. IgA functions by preventing pathogens from adhering to and infecting the epithelial cells at these sites. IgA is also secreted in a nursing mother’s breast milk as well as are IgG and IgM but in lower concentrations. In bodily secretions, IgA is in a dimeric form in which a J-chain and a secretory chain hold two monomers together. The dimeric form is resistant to proteolysis in mucosal secretions.

IgD is the least understood isotype. IgD is found on the surface of B lymphocytes at different stages of maturation and may be involved in the differentiation of these cells. The main function of circulating IgD has not yet been determined. However, mice treated with exogenous anti-IgD antibody display a marked increase in immunoreactivity and secretion of all types of immunoglobulins and several T-cell specific cytokines. High levels of anti-IgD autoantibodies of various subtypes have also been observed in most autoimmune diseases with frequencies of >50%, suggesting that IgD may play an important role in the etiology of these diseases.

IgE is the least common of the serum antibody isotypes. Most of the IgE in the body is bound to the IgE Fc receptors on mast cells. When the IgE on the surface of mast cells binds antigen, it causes the release of various inflammatory substances (e.g., histamine) from the mast cell. The overall effect is the stimulation of inflammation. Asthma and hay fever are two examples of allergic reactions primarily due to antigen binding to IgE.

Cytokines are soluble factors released or secreted by cells. These proteins affect the activity of other cells (paracrine) or the secreting cell itself (autocrine). For example, activated CD4+ T lymphocytes secrete IL-2 which activates itself as well as activating CD8+ T lymphocytes and NK cells. Research has shown that many cytokines (Table 95–5) have a broad spectrum of effects dependent on their concentration, the presence of other factors, and the target cell. New cytokine families and their roles in disease processes are being discovered daily. Cytokines provide communication between the divisions of the immune system. Cytokines produced from APCs generally promote chemotaxis of other cells and induce a state of inflammation. Monocytes, as previously mentioned, use pattern recognition receptors, enabling the immune system to distinguish pathogenic proteins from nonpathogenic proteins through toll-like receptors stimulating T-lymphocyte activation.

Cytokines can also prevent activation or response of immunologic cells. For example, IL-10 is an anti-inflammatory cytokine that is produced in the respiratory tract to prevent IgE synthesis and activation of eosinophils when exposed to benign inhaled particles. In vivo cytokines do not act alone but in combination with other cytokines. For example, activated CD4+ T lymphocytes secrete both IL-2 and interferon-γ which are synergistic in activating NK cells. As shown in Tables 95–1 and 95–5, cytokines are broadly classified as regulatory or hematopoietic growth factors. This classification does not describe all their activities. Granulocyte macrophage-colony stimulating factor (granulocyte-macrophage colony-stimulating factor) released by activated T lymphocytes acts as a hematopoietic growth factor, but also activates granulocytes and macrophages to phagocytize foreign pathogens.

The division of the immune system into the two functional groups does not imply that the divisions do not interact. In order to generate a vigorous immune response, both soluble mediators (e.g., complement, antibody, and cytokines) and cells (e.g., neutrophils, macrophages, dendritic cells, T lymphocytes, and B lymphocytes) are needed. Generally, the innate system will respond first. Dendritic cells, macrophages and neutrophils in the tissues
will recognize pathogen via surface receptors (Fig. 95–2). In order to amplify the immune response, the antigen presenting cells will present antigen to CD4+ T lymphocytes (Figs. 95–3 and 95–4). The activated CD4+ T lymphocytes will then secrete cytokines to activate B lymphocytes, CD8+ T lymphocytes, NK cells, macrophages, and neutrophils. The next section of the chapter discusses the evaluation of the immune system.

**DISEASES OF THE IMMUNE SYSTEM**

Although this chapter is not intended to detail the diseases of the immune system, it is necessary to review the terminology and provide specific examples of diseases of the immune system to understand the role of monitoring and possible intervention with pharmacotherapy. Diseases of the physical defense immune system are often not thought of as diseases of the immune system; however, the loss of normal physical defenses is the most common cause of impaired immunity resulting in infectious sequelae. For example, thick respiratory secretions secondary to altered chloride transport in cystic fibrosis leads to pathogen airway colonization. Primary immunodeficiency diseases are those characterized by either a genetic inability to produce components of the immune system (i.e., severe combined immunodeficiency or hypogammaglobulinemia) or acquired, as seen with HIV infection. Autoimmune diseases result from a dysregulation of a component or a combination of components of the immune system (e.g., rheumatoid arthritis, systemic lupus erythematosus). Autoimmune diseases are often characterized by production of autoantibodies against a particular host structure that is critical for normal function, or loss of tolerance or anergy to a ubiquitous antigen (i.e., gluten in celiac sprue). Often medications that suppress the immune system are necessary to control symptoms and halt autoimmune disease progression. Exposure to immunosuppressant medications in the setting of autoimmune diseases or organ transplantation may reduce disease symptoms but at the cost of the host’s ability to fight off infection or cancer. Exogenous regulation of the immune system must be done judiciously, and we must continue to discover new methods for the appropriate evaluation of immune responses.

**EVALUATION OF THE IMMUNE SYSTEM’S FUNCTION**

Assessment of a patient’s immune function requires knowledge and understanding of multiple components including mechanical defenses, cell phenotypes and cell numbers, and soluble components. Recent developments in biotechnology have allowed for progress in further characterization of immune system components and their functions. This is important because the upregulation and downregulation of immune responses is necessary to treat various disease states. Therefore, pharmacotherapeutic considerations must balance the risk of disrupting normal immunologic homeostasis. Improvements in immune monitoring are necessary for the goal of patient-specific immunologic pharmacotherapy. Despite the technological advances, careful patient evaluations are required to accurately assess the structure and function of the immune system. Specific methods for assessment of patient immune status are discussed below.
Examples of Alteration in Mechanical Leukocyte Counts in Adults

- Reduced gastric pH
- Achlorhydria
- Use of histamine-2 blockers and proton pump inhibitors
- Patients with acquired immunodeficiency syndrome
- Break in skin barrier
- Burns
- Surgical incision
- Penetrating trauma
- Vascular access devices
- Impaired mucociliary function of the lungs
- Smoking
- Impaired esophageal or epiglottal function
- Endotracheal intubation
- Stroke
- Recumbent position
- Altered urine flow
- Urinary stones
- Anatomic deformities obstructing flow
- Bladder catheter
- Anatomic alterations of the heart resulting in turbulent blood flow and endocarditis

### INNATE IMMUNITY: EVALUATION OF MECHANICAL IMMUNODEFENSES

As discussed earlier, the mechanical aspects of host defense are extremely important in protection from infection; therefore, assessment of mechanical defenses is critical. Much of the assessment of mechanical immunodefense is accomplished by recognition of situations where such defense is compromised. Careful patient examination usually reveals the extent of compromise, and laboratory tests are generally not necessary for evaluation of this component. To assess the extent of compromise in mechanical immunodefenses, the clinician should carefully examine the patient and identify the specific types of risks present. Specific examples of altered mechanical defenses are listed in Table 95-6.

### INNATE AND ADAPTIVE IMMUNITY: GROSS EVALUATION OF CELLULAR COMPONENTS

A major aspect of the assessment of immune function relates to the cells of the immune system. Assessment of cells in the clinical setting includes determination of cell type, cell number, and/or function. Generally, determination of the cell types and quantification of the cell numbers are performed first because of the ease of obtaining these results and the common correlation with the clinical situation.

To quickly screen cell numbers, a white blood cell (WBC) count with differential is performed. Normal cell counts are shown in Table 95–7. This simple test often steers the differential diagnosis. In interpreting a WBC with differential, the clinician must consider several factors. A normal cell count does not mean that a leukocyte function is normal. A WBC with differential is performed. Normal cell counts are shown in Table 95–7.

*Cell counts are expressed as cells/mm³ or × 10⁶/L.*

Functional analysis of these cell types is rarely done in routine clinical practice. Patients with suspected functional deficits in these cell types are generally referred to tertiary medical centers for evaluation and treatment.

A routine WBC with differential can determine the total lymphocyte count. Total lymphocyte count has been used as a measure of nutritional status, as this rapidly changes with nutrient loss or repletion. This is a relatively gross measure of a patient’s immune status although it has been correlated to patient outcome and risk of infection.

Lymphocyte populations with different functions or in various stages of activation can be enumerated based on their cell surface markers. These cell surface markers are known as clusters of differentiation (CD). The CD is usually a protein or glycoprotein on the surface of the cell. CD followed by a number designates the marker. Hundreds of monoclonal antibodies have been designed to recognize these cell surface markers. Monoclonal antibodies can be labeled with a fluorescent marker. The labeled monoclonal antibodies are then incubated with the patient’s cells. The antibodies will recognize and bind to the cells expressing the CD of interest, and the cells are then counted using flow cytometry. For flow cytometry, the cell suspension is put under pressure such that the cells flow past a laser in a stream of single cells. The laser will excite the fluorescently labeled antibodies bound to the lymphocytes. A light detector is able to count the labeled cell as the fluorescent tag emits light and determines the size of the cell based on its light...

Scatter. These evaluations are valuable for assessment of patients with immune deficiency states such as AIDS or leukemias, and for patients who have received organ transplants. For example, clinically quantification of CD3+ and CD4+ cells are used, for example, to monitor muromonab, a monoclonal antibody directed against the CD3 receptor. Also the number of CD4+ cells in HIV-positive patients correlates with the risk of and opportunistic infection and delineates the time to initiate antiviral therapy. Some of the more common CD antigens and their respective cellular distribution are listed in Table 95–8. 46 Flow cytometry can be used for leukocyte phenotyping, tumor cell phenotyping, as well as for some types of DNA analysis.

INNATE AND ADAPTIVE IMMUNITY: FUNCTIONAL EVALUATION

Counting the number of cells may help you estimate the function of the immune system, but several disease states exist in which there is an adequate number of cells but they are nonfunctional or they do not produce cytokines to communicate effectively. No single test exists to predict the function of the immune system with 100% accuracy. However, available tests can measure the viability of certain cell lines and communication between cells. Historically, the most common in vivo assay of lymphocyte function is the delayed hypersensitivity skin test. This test specifically evaluates the presence of delayed-type hypersensitivity or the presence of memory T lymphocytes. Specifically, a small amount of antigen, of which the patient is known to have been previously exposed, is administered. Under normal immunologic host conditions, exposure to this amount of antigen in the skin should produce lymphocytic infiltrate into the area within a few hours; followed by additional lymphocyte recruitment and phagocytes (e.g., macrophages, neutrophils) translocation. The maximal intensity of the inflammatory reaction occurs by 24 to 72 hours. This reaction is often referred to as type IV hypersensitivity (i.e., cell mediated; Chapter 97). A delayed-type hypersensitivity reaction is a test of cell-mediated immunity used to assess immunocompetency. The most common method to assess delayed-type hypersensitivity is to administer intradermally a panel of recall antigens. Commonly used antigens include Candida albicans, mumps, trichophyton, tetanus toxoid, and purified protein derivative of tuberculin (PPD). 44 Measurements in millimeters of induration at the site of injection should be taken 48 to 72 hours after placement of the antigens. A reaction is considered positive if the diameter of induration is 2 mm or greater. The degree of sensitivity correlates to the area of induration. 44 Reaction to even a single antigen indicates a functioning cell-mediated immunity. The majority of immunocompetent individuals will show a positive reaction to at least one of these antigens. Possible reasons for not mounting a response to these antigens include congenital T-lymphocyte deficiency, cancer, HIV, or immunosuppressive drug therapy. 45 No response is sometimes mounted because the individual being tested has not been previously exposed to a particular test antigen, although this is rare.

Global assessment of the in vivo immunologic response is also used commonly in solid organ transplantation during the diagnosis and assessment of acute rejection. For example, cellular rejection is detected on gross tissue biopsy by counting the number of lymphocytes present in the tissue and correlating their presence with other clinical findings, such as increasing serum creatinine in kidney transplant.

In vivo assessment of B-lymphocyte function involves immunizing the patient with a protein (e.g., tetanus toxoid) and a polysaccharide (e.g., pneumococcal polysaccharide vaccine) antigen to elicit and measure antibody responses after immunization. Two to 3 weeks after immunization, the patient’s serum is tested for antibodies specific for the immunized antigen. This test measures B-lymphocyte responsiveness to the inoculated antigens but is reserved for patients who are suspected to have impaired B-lymphocyte function. 46

A number of specific in vitro lymphocyte functional assays are used in the research setting. A few assays are performed at specialized clinical laboratories. One of these tests is the lymphocyte proliferation assay. In this assay, lymphocytes are obtained from a patient’s peripheral blood and cultured in vitro. The cells are exposed to nontropic mitogens such as pokeweed mitogen, phytohemagglutinin, or concanavalin A. Then the cells are incubated in growth media containing tritium-labeled (3H) thymidine, a nucleotide used in the synthesis of DNA. Normally in the presence of the mitogens, lymphocytes will be stimulated to proliferate. Proliferating lymphocytes will incorporate 3H thymidine as they replicate DNA. The level of radioactivity of the cells can be measured on a ß-scintillation counter and is proportional to the degree of proliferation. The patient sample needs to be compared to normal, healthy controls’ lymphocytes. Patients with immune deficiencies (AIDS, cancer, etc.) have fewer active or less active lymphocytes, as detected by this test.

A modification of the lymphocyte proliferation assay can be used in allogeneic bone marrow transplantation to evaluate how closely a donor and host are “matched” in order to predict a patient’s risk for developing graft-versus-host disease. A mixed lymphocyte culture (MLC) can be used to assess the potential of the donor cells to attack the host cells, graft-versus-host disease (Chap. 148). In this test, donor cells and host cells are incubated in vitro. The host lymphocytes are irradiated prior to the inoculation so that they cannot proliferate. In vitro, 3H thymidine is provided to the cells and uptake is measured. The degree of uptake correlates to level of proliferation of donor lymphocytes. If the cells are well matched, proliferation is minimal. If the cells are mismatched, proliferation will be noted with the level of proliferation predictive of the potential extent of graft-versus-host disease. With the introduction of DNA-based molecular typing of HLA antigens, the MLC is rarely used today. However, the MLC may play a role in selecting not completely histocompatible donors. 44

The Cytox Immune Cell Function assay was recently FDA approved as a novel test used to determine the magnitude of suppression of CD4+ cells. 45 Briefly, activity of CD4+ cells is measured by quantification of the amount of ATP produced and characterized as high, medium, or low. 46 Initial, retrospective experience has been reported in the solid organ transplant population. Although this assay is in its clinical infancy, it is one of the first functional assays aimed at assessing individual patient response to immunosuppressive therapy. This type of testing may allow for tailoring of immunosuppression.
More recently, evaluation of immune cell activity, such as factor forkhead box P3 (FOXP3) T-regulatory cell activity has been used to evaluate the incidence and severity of acute rejection based on elevated FOXP3 mRNA expression in urine and tissue cell samples. T-regulatory cells control autoimmune reactions; therefore, the presence of these cells in an allograft may indicate a level of “tolerance” to the donor tissue. Tolerance, basically, is a state in which the body knows that foreign tissue (e.g., kidney transplant) exists but does not attack it. Initial studies have evaluated biopsy samples from organ transplant recipient and correlated them with levels of FOXP3. Early evidence suggests that FOXP3 is present only during periods of inflammation, such as rejection, and potentially projects the allograft tissue. In addition to the tests described above, a number of other tests and assays have been devised to evaluate the function of CD8+ T lymphocytes, NK cells, and monocytes/macrophages. Although these evaluations are not commonly performed, they may be helpful in some specific diseases and will likely be the way in which we monitor and detect immunologic events in the future. A thorough discussion of these tests is available.

EVALUATION OF CYTOKINES AND CHEMOKINES

Often disease states involving the loss or upregulation of cytokines and chemokines are overlooked as diseases of the immune system. However, as we have just reviewed, cytokines and chemokines are essential components of both the innate and adaptive immune systems and provide the communication linking them together. Assays of humoral components may be either quantitative to determine the absolute concentration of the factor or qualitative to determine the function of the component.

IMMUNOGLOBULINS

Measurement of immunoglobulins is a direct measure of B-cell function. The most common evaluation of immunoglobulins is the estimation of total immunoglobulin. This is approximated by subtracting the albumin concentration from the total protein concentration in serum. This difference gives a gross estimation of the total immunoglobulin. This is approximated by subfunction. The most common evaluation of immunoglobulins is the measurement of immunoglobulins. Measurement of immunoglobulins is a direct measure of B-cell function of the component. A polyclonal hypergammaglobulinemia (e.g., chronic inflammatory conditions such as systemic lupus erythematosus or chronic active hepatitis). Total immunoglobulin or γ-globulin concentrations cannot be used to measure antigen specific antibodies or specific isotypes, although other evaluations can.

In a patient suspected of having humoral immune deficiency or B-lymphocyte failure (i.e., primary and secondary hypogammaglobulinemia), specific immunoglobulin isotypes in the plasma should be measured.

There are many indications for the measurement of antigen-specific antibody. Some common indications are listed in Table 95–9. Methods to perform these measurements include enzyme-linked immunosorbent assay (ELISA), radioimmunoassay (RIA), and radioallergosorbent test (RAST) (Fig. 95–7). The most common reason to measure antigen-specific antibody is to determine whether or not a patient has been exposed to an infectious agent. Generally, IgM antibodies directed against the pathogen indicate an active or recent infection while IgG antibodies directed against the pathogen indicate prior exposure. This observation correlates with our understanding of B-lymphocyte responses in which plasma cells produce IgM initially in response to an infection, but later switches to IgG. Therefore, IgM antibodies will be

FIGURE 95-7. Enzyme-linked immunosorbent assay (ELISA). ELISA is a commonly used method for measuring concentrations of a wide variety of substances. To measure the concentration of antibodies to a particular antigen, the antigen is coated onto a solid phase, such as a microtiter plate or beads. If the purpose of the assay is to measure the concentration of antigen in solution, an antibody to the antigen is coated on the solid phase. The biologic fluid, often sera, is added to the wells. An enzyme-labeled anti-human antibody is added next. Finally, the chromogenic substrate for the enzyme is added. The intensity of the color as measured spectrophotometrically is proportional to the concentration of the antibody in the biologic fluid.
present during an active infection and shortly after recovery from the infection. IgG concentrations will increase at the end of the primary exposure, but predominate after a second exposure. IgG predominates after a second exposure because memory B lymphocytes predominately secrete IgG in the serum. Other uses of antigen-specific antibody include determining if a patient has had exposure and is likely to be protected from infection (e.g., hepatitis A virus) or to determine adequate response to vaccination (e.g., hepatitis B vaccine). Clinically, measurement of antihuman IgG antibodies is used pre- and post-solid organ transplant to detect and potentially predict allograft compatibility and treat antibody-mediated rejection.

Antigen-specific IgE is commonly measured in patients with allergies. Because the presence of antigen-specific IgE is related to clinical allergy, measurement of these antibodies can be helpful in diagnosing allergies and determining offending substances. A standard method for determination of allergen-specific IgE is the RAST. The basic technique involves adding the antigen of interest, which is bound to beads or disks, to the patient’s serum. After precipitation and several washings, the antibody bound to the bead or disk is isolated. Finally, a radiolabeled antibody that binds to IgE is added. After further washings, the radiolabeled antibody bound to IgE, which is bound to the antigen on the bead or disk, is counted on a gamma counter.

Antigen skin testing is the preferred method to determine the presence of allergen-specific IgE. When it is produced, IgE binds to high-affinity IgE Fc receptors on basophils or mast cells. Contact of an allergen with the specific IgE on the basophil or mast cell surface causes activation of these cells and the release of inflammatory mediators (e.g., histamine). When this occurs systemically, it can cause anaphylaxis. When it occurs in a confined area such as the skin, erythema and induration are observed within a few minutes of allergen injection. This is the principle used for detection of penicillin allergy as well as for environmental or food allergies. A positive skin reaction (≥5 mm of induration) within 15 to 20 minutes is indicative of the presence of allergen-specific IgE.

There are four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4 that make up 65%, 20%, 10%, and 5% of total plasma IgG, respectively. Concentrations of the subclasses are often measured in patients with suspected primary and secondary hypogammaglobulinemia. IgG2 and IgG4 deficiencies are associated with chronic infections. IgG4 deficiencies are also associated with autoimmune disorders.

**COMPLEMENT SYSTEM**

The complement system consists of a group of over 30 different proteins involved in lysing and opsonizing invading pathogens as well as serving as chemotactic factors. Numbers following the letter C (e.g., C1, C2) name the various proteins of the complement system. A test for the global assessment of the complement system is the CH$_{50}$, the total hemolytic complement test. This test is based on the premise that complement is needed for a rabbit anti-sheep antibody to lyse sheep red blood cells. The source of the complement is the patient’s serum. Each laboratory standardizes the test so normal ranges vary, but a standard curve is developed by adding titrated amounts of sera and measuring the amount of hemolysis. The hemolysis is determined with a spectrophotometer to measure the amount of hemoglobin released. The patient’s serum is then tested, and the amount of serum that is needed to lyse 50% of the red blood cells is reported as the CH$_{50}$. This test does not provide an indication of the function of any specific complement component but is used as a screening test for any complement system defects. If a defect is found, individual complement proteins can then be evaluated by functional or immunochemical methods. Assessment of the complement system is important in patients suspected of having humoral immune deficiencies (i.e., recurrent infections).

Several disease states can alter complement concentrations. Low complement concentrations are frequently found during states of acute inflammation (e.g., systemic lupus erythematosus [SLE], rheumatoid arthritis, collagen vascular disorders, poststreptococcal glomerulonephritis, and subacute bacterial endocarditis). These states of apparent low complement concentrations are generally due to high rates of complement utilization or consumption that cannot be compensated for by increased complement synthesis.

Since the liver is the primary source of several components of the complement system (i.e., C2, C3, C4, factors B and D), a global decrease in complement factors occurs in severe liver failure. Inherited complement deficiencies have been described in patients with SLE, autoimmune diseases, recurrent gonococcal and meningococcal infections, membranoproliferative glomerulonephritis, and hereditary angioedema.

Clinically, the complement system has been used to diagnose and treat solid organ rejection. Antibody-mediated or humoral rejection is evaluated by quantifying the amount of donor MHC specific antibody present in the recipient’s serum. The presence of donor-specific antibodies is correlated with evidence of antibody-mediated rejection on tissue samples. This is characterized by the presence of complement split products, namely C4d, which is present after complement-dependent antibody-mediated rejection. C4d covalently binds to the allograft tissue and can be stained for on biopsy samples. Unfortunately unless biopsy findings can be correlated with a clinical finding consistent with rejection, the presence of C4d and its prognosis on long-term allograft function are unknown.

**CYTOKINES**

Cytokines are an important means of communication among cells of the immune system and other organ systems. Multiple cytokines with overlapping and redundant functions have been identified. Methods to detect and measure cytokines in biological samples have been developed. For nearly all the currently identified cytokines, commercial kits are available to measure endogenous and exogenously administered cytokines. The most common and preferable methods to measure cytokines are ELISAs and RIAs. ELISAs and RIAs are easy to run and measure immunoactivity but not biologic activity (Fig. 95–7). Bioassays measure biologic activity, but are cumbersome and extremely variable. Using ELISA, we are able to measure only how much cytokine was produced by the cells in the culture. An ELISPOT is an enzyme-linked assay for detecting and enumerating cytokine-producing leukocytes. In contrast to conventional ELISA, ELISPOT allows the user to detect absolute numbers and frequencies of cytokine secreting leukocytes.

We are still at the very early stages of interpreting the clinical relevance of endogenous cytokine concentrations. Not only is the immune system affected by cytokines such as IL-1, IL-6, TNF-α, but other systems (skeletal, endocrine, central nervous system) are also affected. Therefore, measurement of cytokine concentrations may be important in the evaluation of other systems as well as the immune system.

Administering cytokines in clinical practice may change not only the concentration of that particular cytokine, but also the resultant concentration of other cytokines. For example, systemic administration of GM-CSF to patients not only increases concentrations of GM-CSF but also of TNF-α, IL-6, IL-8, macrophage colony-stimulating factor and erythropoietin. Secondary endogenous cytokine release should be taken into account when considering the therapeutic effects of these agents and when monitoring cytokine concentrations.
In the future, tissue concentrations as well as blood concentrations may be measured. For example, while many centers currently measure cyclosporine concentrations to estimate the potential for immunosuppressive effects, it may be advantageous to monitor IL-2 concentrations. One of the primary actions of cyclosporine is the inhibition of IL-2 production. Furthermore, perhaps it would be beneficial to measure tissue concentrations of IL-2 in the transplanted organ to get a better estimate of the extent of immunologic suppression.

**SOLUBLE RECEPTORS AND RECEPTOR ANTAGONISTS**

The inflammatory response is highly regulated. The activity of cytokines, their receptors, and their antagonists are in a delicate balance. Although cytokine receptors are typically thought of as being found on the target cell, soluble cytokine receptors can modulate the activity of cytokines in at least two ways: (1) acting as antiinflammatory agents by binding cytokines with high affinity, but without biological activity; (2) augmenting cytokine activity by prolonging the cytokines plasma half-life and even maintaining agonist activity on cells that do not inherently respond to the cytokine. Finally, antagonists to cytokine receptors have been identified.

Tumor necrosis factor-α (TNF-α) plays a central role in the inflammatory response by both increasing the expression of adhesion molecules in the tissues and by stimulating production of pro-inflammatory cytokines (e.g., IL-2, IL-8), prostaglandins, and nitric oxide. Soluble tumor necrosis factor receptors (sTNFRs) act primarily as inhibitors of TNF by preventing TNF from binding to the membrane-bound TNFRs, or by causing the cells to shed the receptor from the surface of the cell so that it can no longer serve as a signaling molecule. Both monoclonal antibodies against TNF (e.g., infliximab) and sTNFRs (e.g., etanercept) have been shown to modulate the activity of TNF and are used clinically for the treatment of autoimmune diseases.

The best characterized receptor-binding antagonist is the interleukin-1 receptor antagonist (IL-1RA). IL-1RA blocks the binding of IL-1 to its receptor by competing for the same binding site, but IL-1RA does not possess agonist activity. A recombinant IL-1RA, anakinra, is used clinically for the treatment of severe rheumatoid arthritis.

Our developing understanding of soluble receptors and receptor antagonists allows us to better mimic natural mechanisms for immunomodulation.

**MODULATION OF THE IMMUNE RESPONSE**

Modulation of the immune response through administration of pharmacological agents or with blood product components does not come without a risk gained with the benefit. Providing supplementation to the immune system, for example during periods of sepsis with recombinant activated protein C (drotrecogin alfa) provides increased levels of protein C which decrease levels of pro-inflammatory IL-6 potentially limiting the effects of the immune reaction and preventing end organ damage at the cost of bleeding for over exposure to protein C. While TNF inhibitors interfering with the immune system to halt the damage of an autoimmune disorder may suppress symptoms, it places the patient at risk for opportunistic viral infections. Many of our newer biological agents directed at a pathway in the immune system are genetically engineered from animals and humanized to increase their biological effectiveness. As a result, these agents can serve as antigens to the immune system and display variable effectiveness between and among patients over time. For example, an agent commonly used in solid organ transplantation is rabbit anti-thymocyte globulin, which is a polyclonal antibody directed against lymphocytes which given at the time of transplant or to treat rejection. Patients with previous exposure to this agent may have developed antibodies against the rabbit epitope of the drug. This results in either a decrease in the effectiveness of the drug, because it is bound by antibody or production of an immunologic reaction, commonly manifested by antibody-antigen complex deposition in the kidneys and joints producing high fevers and renal failure. Based on the very few examples presented here, one can understand why manipulation of the immune system must be carefully assessed and appropriate patient instruction given.

**IMMUNOSUPPRESSION**

Immunosuppression was first developed and used to allow transplantation of foreign tissues or to treat malignancies of the immune system. Today, the number of compounds and disease states in which the immune system is implicated is virtually unquantifiable. Therefore a thorough review of these drugs is beyond the scope of this chapter. These medications are usually very expensive and associated with potentially serious adverse effects. Immunosuppressants block critical steps of the immune response, and patients must be counseled on their risk of infection and the plan to monitor effectiveness of the immunosuppressant. Several key concepts and questions can be used to help clinicians discern the potential benefits and ramifications of administering any immunosuppressant. These include: (1) what is its mechanism of action, (2) what arm of the immune system does it affect, (3) when is its onset of action, (4) how was this compound derived and does it have the potential to stimulate antibody production if the patient is re-exposed, (5) is this compound’s effect dose or duration related, (6) what type of infection is my patient at risk for and do I need to administer prophylactic medications, and (7) how do I monitor the biological effect of this compound?

**IMMUNOPOTENTIATION**

In an attempt to restore normal immune system function or to activate the immune system, immunopotentiators are often used. The best example of immunopotentiation of the immune system is the practice of immunizations. Active immunization with a vaccine or toxoid induces the host’s immune system to confer protection against a pathogen (e.g., hepatitis A, hepatitis B, diphtheria toxoid, etc.). This process requires the uptake of the immunogenic epitope by antigen presenting cells followed by presentation to CD4+ T lymphocytes and the subsequent development of either a cellular or humoral immune response.

In contrast to active immunization, passive immunity entails the administration of human immunoglobulin to provide short-term protection to individuals who will be or have been exposed to a pathogen. Intravenous immunoglobulin (IVIG) consists of >90% polyclonal IgG that is prepared from donated plasma. In patients with primary or secondary hypogammaglobulinemia, IVIG restores circulating IgG concentrations thus decreasing the incidence of infections in these patients. In addition to restoring IgG concentrations, IVIG can potentially immunomodulate the immune response. For example, in immune thrombocytopenic purpura, an autoantibody directed against the platelet leads to the destruction of the platelets by antibody-dependent cellular cytotoxicity. IVIG saturates the Fc receptors on phagocytic cells, thereby preventing the engulfment of autoantibody-opsonized platelets. IVIG can also
SUMMARY

Our understanding of the immune system has dramatically increased over the last decade. An immune response encompasses dynamic events involving both immunologic cells (e.g., phagocytes, lymphocytes) and soluble mediators (e.g., complement, cytokines, antibodies). A better understanding of the normal immune response allows us to investigate the pathophysiology of diseases in which the immune response is inappropriate. All clinicians need a basic understanding of the immune system and a familiarity with parameters to monitor immune system function in order to refine the development of immunologic treatments for diseases ranging from diabetes mellitus to collagen vascular disorders to cancer.

REFERENCES

This page intentionally left blank
The collagen–vascular diseases are a heterogeneous group of diseases that can involve the musculoskeletal system, integument, and blood vessels. Each collagen–vascular disease has its own set of diagnostic criteria, although diagnosis can be difficult because of overlapping and nonspecific clinical presentations. The etiology of the various collagen–vascular diseases is often unknown, but the immune system usually is involved in the pathogenesis and manifestations of the disease. Therefore, pharmacotherapy usually includes antiinflammatory agents with or without immunosuppressive drugs.

Although the prevalence of other collagen–vascular diseases may be greater than that of systemic lupus erythematosus (SLE) (e.g., polymyalgia rheumatica), SLE is discussed most extensively in this chapter because it is a major collagen–vascular disease with numerous clinical manifestations, its pharmacotherapy can be complex, and a plethora of data is available on the therapy of SLE. As all the diseases discussed in this chapter have an immune-mediated pathogenesis, the therapeutic principles of SLE can be applied to other autoimmune collagen–vascular diseases. The collagen–vascular diseases discussed include systemic sclerosis, polymyositis/dermatomyositis, polymyalgia rheumatica, and drug-induced vasculitis; these were chosen because they are seen in general practice.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a fluctuating multisystem disease with a diversity of clinical presentations. Abnormal immunologic function and formation of antibodies against “self-antigens” underlie the pathogenesis of SLE.

The term lupus erythematosus was first used in 1851 by Cazenave, a Frenchman who described an illness in a patient with manifestations occurring in the skin. It is not surprising that SLE was first recognized as a skin disorder because cutaneous manifestations constitute one of the most common clinical features of the disease. Further descriptions by Kaposi and Osler in the late 1800s led to the concept of a multisystem disease as it became recognized that patients developed complications in other organ systems.

The hallmark of SLE is the development of autoantibodies to cellular nuclear components, resulting in chronic inflammatory autoimmune disease. Symptoms and organ involvement depend on the nature of the autoantibodies.

SLE has a wide spectrum of symptoms and organ system involvement, making therapy highly patient specific. In addition, the signs and symptoms will fluctuate over time.

The wide spectrum of symptoms and organ system involvement makes pharmacotherapy difficult because therapy must be individualized based on each patient’s disease activity.

There is a paucity of quality evidence for the treatment of SLE except for lupus nephritis.

Almost all classes of medications, including antiinflammatory and immunosuppressive agents, are reported to cause vasculitis in most major organ systems.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

EPIEDEMOLOGY

The incidence of SLE varies among ethnic groups with the annual incidence in adults ranging from 1.9 to 5.6 per 100,000 persons per year, with a prevalence of approximately 50 cases per 100,000 persons. The disease occurs predominantly in women, with a reported female-to-male ratio approaching 10:1. Those afflicted with SLE are usually diagnosed between the ages of 15 and 45. SLE is reported to be less prevalent in whites than in other ethnic groups, including blacks, Hispanics, Native Americans, and Asians. Although the most typical SLE patient is a young adult woman, the disease can occur in people of any age or race and either gender.

ETIOLOGY

The etiology of abnormal autoantibody production and development of SLE is still unknown. Genetic, environmental, and hormonal factors all may play a role in loss of “self-tolerance”
and expression of disease. A popular theory is that autoimmune disease such as SLE develops in genetically susceptible individuals after exposure to a triggering agent, possibly something in the environment.\(^7\)–\(^9\)

Genetic analysis shows that at least four susceptibility genes are required for the expression of lupus in humans.\(^3\) Familial and twin studies indicate a genetic predisposition for the development of SLE. First-degree relatives of SLE patients are about 20 times more likely to develop SLE than the general population; more than 5% of cases are familial. The concordance rate among identical twins ranges from 24% to 58%, compared with 3% to 10% for nonidentical twins.\(^10\) Multiple genes contribute to SLE susceptibility, and at least 100 genes have been linked to SLE in humans. Evidence indicates that major histocompatibility complex genes, particularly several human leukocyte antigen genes, may be important in lupus. However, nonmajor histocompatibility complex genes, such as immunoglobulin receptor genes and mannose-binding protein genes, also may contribute to disease susceptibility.\(^9\),\(^10\)

Environmental agents that may induce or activate SLE include sunlight (i.e., ultraviolet light), drugs, chemicals such as hydrazine (found in tobacco) and aromatic amines (found in hair dyes), diet, environmental estrogens, and infection with viruses or bacteria.\(^3\) A number of viruses have been implicated as causative agents in genetically susceptible people with significant data identifying the Epstein Barr virus as a causative agent.\(^11\),\(^15\) Additionally, androgen may inhibit and estrogen may enhance the expression of autoimmunity, and elevated circulating prolactin levels have been associated with lupus in males and females.\(^9\),\(^12\)

### PATHOPHYSIOLOGY

2. SLE represents a clinical syndrome rather than a discrete disease with a unique pathogenesis. SLE has a large spectrum of symptoms and organ system involvement.\(^1\) A major event in the development of SLE is excessive and abnormal autoantibody production and the formation of immune complexes. Patients may develop autoantibodies against multiple nuclear, cytoplasmic, and surface components of multiple types of cells in various organ systems in addition to soluble markers such as immunoglobulin G and coagulation factors; these autoantibodies account for the multiple-organ-system involvement of the disease.\(^7\)

Excessive autoantibody production results from hyperactive B lymphocytes. Multiple mechanisms likely lead to B-cell hyperactivity, including loss of immune self-tolerance and high antigenic load consisting of environmental and self-antigens presented to B cells by other B cells or specific antigen-presenting cells, a shift of T-helper type 1 cells to T-helper type 2 cells that further enhance B-cell antibody production, and defective B-cell suppression. Impairment in other immune regulatory processes involving T lymphocytes (suppressor T cells), cytokines (e.g., interleukins, interferon-\(\gamma\), tumor necrosis factor-\(\alpha\), transforming growth factor-\(\beta\)), and natural killer cells also may be involved.\(^11\),\(^14\)

Many autoantibodies are directed against nuclear constituents of the cell; collectively, they are called antinuclear antibodies. Several antinuclear antibodies are important because their presence or absence may aid in the diagnostic and clinical evaluation of patients with SLE. The SLE patient may have more than one antigen-specific antinuclear antibody in the patient’s serum and tissues.\(^15\) These are antibodies against such nuclear constituents as double-stranded, or native, DNA (dsDNA); single-stranded, or denatured, DNA (ssDNA); and RNA. Four RNA-associated antigens frequently occurring in SLE are the Smith (Sm) antigen, the small nuclear ribonucleoprotein (snRNP), the Ro (SS-A) antigen, and the La (SS-B) antigen.\(^12\),\(^16\) Histone, a basic component of chromatin and nucleosomes, is another important nuclear component against which antinuclear antibodies are formed in lupus patients. Antibodies to dsDNA are highly specific for SLE and are present in 70% to 80% of patients.\(^12\) Antibodies also may be directed against the phospholipid moiety of the prothrombin

| **TABLE 96-1** Revised Criteria for Classification of Systemic Lupus Erythematosus* |
|-------------------------------|--------------------------|
| **Criterion**                 | **Definition**           |
| Malar rash                    | Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds |
| Discoid rash                  | Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions |
| Photosensitivity              | Skin rash as a result of unusual reaction to sunlight; by patient history or physician observations |
| Oral ulcers                   | Oral or nasopharyngeal ulceration, usually painless, observed by a physician |
| Arthritis                     | Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion |
| Serositis                     | Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion |
|                                 | Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion |
| Renal disorder                | Persistent proteinuria >0.5 g/day (500 mg/day) or >3+ if quantitation not performed |
|                                 | or Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed |
| Neurologic disorder           | Seizures—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance |
|                                 | or Psychosis—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance |
| Hematologic disorder          | Hemolytic anemia—with reticulocytosis |
|                                 | or Leukopenia—fewer than 4,000 cells/mm\(^3\) (4 × 10\(^9\)/L) total on two or more occasions |
|                                 | or Lymphopenia—fewer than 1,500 cells/mm\(^3\) (1.5 × 10\(^9\)/L) on two or more occasions |
|                                 | or Thrombocytopenia—fewer than 100,000/mm\(^3\) (100 × 10\(^9\)/L) in the absence of offending drugs |
| Immunologic disorder          | Anti-DNA; antibody to native DNA in abnormal titer |
|                                 | or Anti-Smith (Sm) antigen; presence of antibody to Sm nuclear antigen |
|                                 | or Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin (Ig)G or IgM antiphospholipid antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by Treponema pallidum immobilization or fluorescent treponemal antibody absorption test |
| Antinuclear                    | An abnormal titer of antinuclear antibody by immunofluorescence or an antibody equivalent assay at any point in time in the absence of drugs known to be associated with “drug-induced lupus” syndrome |

*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation. From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1982;25:1274 and Hochberg MC. Updating the American College of Rheumatology Revised Criteria for the Classification of Systemic Lupus Erythematosus. Arthritis Rheum 1997;40:1725, with permission.
activator complex (lupus anticoagulant) and against cardiolipin. The lupus anticoagulant and antcardiolipin antibodies constitute the two main types in a group of autoantibodies called antiphospholipid antibodies.

These autoantibodies often are present many years before the diagnosis of SLE. These autoantibodies often precede the onset of SLE by many years, whereas anti-Sm and anti-snRNP antibodies appear only months before diagnosis, usually when clinical symptoms begin to manifest. Immune dysregulation leading to B-cell hyperactivity and subsequent production of pathogenic autoantibodies, coupled with defective clearance of apoptotic cells, followed by immune-complex formation, complement activation, and defective clearance of immune complexes all lead to inflammatory reactions that ultimately result in tissue injury and damage. Figure 96–1 is an overview of the pathogenesis of SLE.

CLINICAL PRESENTATION

As mentioned previously, SLE is a multisystem disease. Below (see Clinical Presentation of Systemic Lupus Erythematosus) are many of the signs and symptoms and incidences for patients with SLE. Although certain of these may be more common than others, each patient presents differently, and the course of the disease is highly unpredictable. Furthermore, SLE is not static, and most patients have fluctuations or flare-ups during the course of the disease.

Nonspecific signs and symptoms such as fatigue, fever, anorexia, and weight loss are seen frequently for patients with active disease. Musculoskeletal involvement (e.g., arthralgia, myalgia, and arthritis) is very common in SLE, with fever, malaise, or arthralgia frequently the chief complaint on initial presentation of the disease. All major and minor joints may be affected, and the pattern of arthritis is often recurrent and of short duration, presenting mainly as joint stiffness, pain, and sometimes inflammation. Objective evidence of musculoskeletal disease often is missing, although a few patients may present with deforming arthritis or subcutaneous nodules.

Manifestations in the skin are very common in lupus. The most well-known of these is the butterfly rash, which occurs over the bridge of the nose and the malar eminences and is present in 50% of patients at some time during the disease. The classic butterfly rash often is observed after sun exposure. In fact, photosensitivity is common to many SLE patients who present with cutaneous manifestations. Skin lesions characteristic of discoid lupus occur in up to 20% of patients with SLE and may occur without other clinical or serologic evidence of lupus. Some individuals develop subacute cutaneous lupus erythematosus on exposure to sunlight. Other cutaneous manifestations include vasculitis (which may be ulcerative), oral ulcers, Raynaud’s phenomenon, and alopecia.

Another common source of symptomatology in SLE is the pulmonary system, with manifestations such as pleurisy, coughing, and dyspnea. Pleurisy may present as pleuritic pain, a pleural rub, or a pleural effusion that usually is exudative in nature. Lupus pneumonitis may present acutely with fever, dyspnea, tachypnea, cough, rale, and patchy infiltrates or chronically with interstitial fibrosis. Pulmonary hypertension associated with SLE is more common than previously thought, which is likely a result of asymptomatic increases in pulmonary artery pressures being more common than symptomatic increases. Patients with SLE-associated pulmonary hypertension have a poor prognosis. Pulmonary embolism also should be ruled out for any SLE patient presenting with pleuritic chest pain and dyspnea.

Cardiac manifestations of SLE often present as pericarditis, myocarditis, electrocardiographic changes, or valvular heart disease, including the classic cardiac lesion of Libman-Sacks endocarditis (nonbacterial verrucous endocarditis). Coronary artery disease (CAD) is being seen in SLE with increasing frequency as the life expectancy of SLE patients increases. The development of heart
Corticosteroid therapy and immunosuppressive therapy are also believed to be contributing factors in the development of these cardiac risk factors. Although hypertension, obesity, and hyperlipidemia are common for SLE patients, these traditional risk factors do not account for the strikingly high cardiovascular event rate found in some recent studies. Other SLE-related risk factors highlight the importance of autoimmunity and inflammation in the pathogenesis of accelerated atherosclerotic cardiovascular disease. Additionally, two studies reported that long-term corticosteroid therapy was not associated with a significantly increased risk of accelerated atherosclerosis. In fact, one of the studies found that patients with higher mean daily doses of prednisone and more frequent use of other common therapies for SLE exhibited less plaque formation, which suggests that more aggressive control of disease activity actually may help to prevent CAD.
Epidemiologic characteristics, clinical signs and symptoms, and common laboratory abnormalities are all used in the diagnosis of SLE.

Once the disease is suspected, serologic tests may be helpful in making the diagnosis. A serologic test used extensively to aid in the diagnosis of SLE is the fluorescent antinuclear antibody (ANA) test. Nearly all SLE patients are ANA positive, but other diseases also can be associated with a positive test (Table 96–2). However, in other diseases, many of the positive ANA tests are of a lower titer. The pattern of immunofluorescence of the ANA test also may be of diagnostic value (Table 96–2), with a peripheral (also called rim) pattern being specific for SLE. Detecting antibodies to specific nuclear constituents also may be useful diagnostically. Antibodies to native DNA (dsDNA) and to Sm antigen are quite specific for and are considered diagnostic of SLE.9,28,29

**PROGNOSIS**

In earlier years, SLE was associated with a poor prognosis. For example, three decades ago 5-year survival was approximately 83% and 10-year survival was approximately 76%.4 Today, as a result of improved treatment and improved diagnostic techniques that allow earlier diagnosis, the approximate 5-year survival rate is 96%, and the 15-year survival rate is 76%.30 The natural course of SLE has changed dramatically not only because of improved therapies but also because of improvement in ability to manage patients with kidney disease (e.g., dialysis), infection, and CAD. However, complications of immunosuppressive treatment, CAD, and infection are still among the leading causes of death among SLE patients.30

**TREATMENT**

### Systemic Lupus Erythematosus

Desired treatment outcomes for the patient with SLE are two-fold: (1) management of symptoms and induction of remission during times of disease flare and (2) maintenance of remission for as long as possible between disease flares. Figure 96–2 outlines an approach to the management of the patient with SLE. Because of the variability in clinical presentation of disease, treatment will vary accordingly and should be highly individualized. Optimal care of the patient with SLE will include education and support services in addition to the nonpharmacologic and pharmacologic

![Figure 96-2](image-url)
treatments discussed below. Numerous lupus organizations exist throughout the world and can be located by contacting the Lupus Foundation of America (http://www.lupus.org), the Arthritis Foundation (http://www.arthritis.org), and Lupus Canada (http://www.lupuscanada.org).

### NONPHARMACOLOGIC THERAPY

Several nonpharmacologic measures can be employed to manage symptoms and help maintain remission. Fatigue is a common symptom for patients with lupus. A balanced routine of rest and exercise, while avoiding overexertion, is essential in managing fatigue. Avoidance of smoking may be particularly important because hydrazines in tobacco smoke may be an environmental trigger of lupus and likely contribute to accelerated CAD. Smoking also has been associated with increased disease activity for SLE patients. No specific dietary measures are known to clearly affect disease. Therefore, for many patients with mild disease, initial exposure limitation should be individualized.

### PHARMACOLOGIC THERAPY

Drug therapy for SLE is often designed to suppress the immune response and inflammation. Except for lupus nephritis, large controlled clinical trials comparing treatment options for SLE are needed. Table 96–3 lists common agents and doses used to control SLE. In general, the choice of drug therapy depends on the extent and severity of disease. Table 96–4 describes select monitoring parameters and adverse events for many of the drugs used to treat collagen-vascular diseases.

#### Nonsteroidal Antiinflammatory Drugs

As discussed earlier, signs and symptoms such as fever, arthritis, and serositis are among the most common for patients with active disease. Therefore, for many patients with mild disease, initial

treatment with a nonsteroidal antiinflammatory drug (NSAID) is a logical choice. The choice of NSAIDs in SLE is empirical. The dose used should be adequate to provide antiinflammatory effects, although low-dose aspirin may be useful in the management of patients with antiphospholipid syndrome.25

Nonselective cyclooxygenase NSAIDs significantly increase the risk of gastric irritation and peptic ulceration. Coprescribing with a gastroprotective agent such as a proton pump inhibitor may be beneficial. Patients with SLE taking NSAIDs may experience a decline in renal function because of drug effects and not the underlying disease. NSAIDs can decrease renal blood flow and glomerular filtration rates and should be used cautiously for patients with nephritis. Awareness of this adverse effect is important because declining renal function may be attributed mistakenly to progression of lupus nephritis. Patients with SLE have a higher incidence of hepatotoxicity than do other patients taking traditional NSAIDs. The use of NSAIDs is also associated with aseptic meningitis in SLE patients.34

**Antimalarial Drugs**

Antimalarial agents such as chloroquine and hydroxychloroquine have been used successfully in the management of discoid lupus and SLE. A few controlled trials provide evidence for the role of antimalarial therapy in controlling disease exacerbations and as steroid-sparing agents.35 In general, the manifestations of SLE that can be managed with antimalarials are cutaneous manifestations, arthralgia, fatigue, and fever.1,31 Because these drugs are not effective immediately, they are best used in long-term management. Response to chloroquine occurs within 1 to 3 months, whereas the maximal effect of hydroxychloroquine may not occur for 6 to 12 months.30 Hydroxychloroquine is probably safer than chloroquine and is considered the antimalarial of first choice.

The mechanism of action of the antimalarial drugs is uncertain. It has been proposed that antimalarials interfere with T-lymphocyte activation.36 Other effects of antimalarials that may benefit patients with SLE include inhibition of cytokines, decreased sensitivity to ultraviolet light, antiinflammatory activity, antplatelet effects, and antihyperlipidemic activity.32,36

Dosage and duration of therapy depend on patient response, tolerance of side effects, and development of retinal toxicity, which is a potentially irreversible adverse reaction associated with long-term therapy, especially with chloroquine. Current recommended doses of antimalarials in SLE are hydroxychloroquine 200 to 400 mg/day and chloroquine 250 to 500 mg/day. After 1 or 2 years of treatment, gradual tapering of dosage can be attempted. Some patients may require only 1 or 2 tablets per week to suppress cutaneous manifestations.36

Side effects of these drugs include CNS effects (e.g., headache, nervousness, insomnia, and others), rashes, dermatitis, pigmentedary changes of the skin and hair, gastrointestinal disturbance (e.g., nausea), and reversible ocular toxicities such as cycloplegia and corneal deposits. Potentially serious retinal toxicity is uncommon when the currently recommended doses are used and is least common with hydroxychloroquine.36 However, because of the possibility of permanent damage associated with the retinopathy, an ophthalmologic evaluation should be done at baseline and every 3 months when chloroquine is used and every 12 months when hydroxychloroquine is used.36

**Corticosteroids**

Corticosteroid therapy is commonplace in therapeutic regimens for SLE. Although evidence for improved survival with corticosteroid therapy is inadequate, these agents are known to suppress the clinical expression of disease and are considered by many to be a major factor in the improved prognosis in recent years. Most controlled trials of corticosteroid therapy have been conducted for patients with severe lupus nephritis, but evidence suggests that corticosteroids are also effective in the management of severe cases of CNS disease, pneumonitis, myositis, vasculitis, thrombocytopenia, and other clinical manifestations.37

A patient with the diagnosis of SLE does not automatically require corticosteroid therapy. Mild disease with such manifestations as fever, arthralgia, pleuritis, or skin manifestations may respond adequately to NSAIDs or antimalarials, but patients with clinical manifestations that are more serious or unresponsive to other drugs usually require corticosteroids.

The goal of treatment with corticosteroids in SLE is to suppress and maintain suppression of active disease with the lowest dose possible. For patients with mild disease, low-dose therapy (prednisone 10 to 20 mg/day) is adequate,36,37 but for patients with more severe disease (severe hemolytic anemia or cardiac involvement), higher doses, such as prednisone 1 to 2 mg/kg daily, may be required. Once adequate suppression of disease is achieved, the dose should be tapered to the minimum amount required for continued disease suppression. When analyzing the need to treat with corticosteroids, the clinician should consider other conditions that may increase the risk of corticosteroid therapy, such as infection, hypertension, atherosclerotic disease, diabetes, obesity, osteoporosis, and psychiatric disease.

Steroid pulse therapy is the administration of short-term, high-dose intravenous corticosteroids with the goal of inducing remission in SLE patients with serious, life-threatening disease, such as severe active nephritis, CNS involvement, or hemolytic disease. A standard pulse regimen consists of intravenous methylprednisolone 500 to 1,000 mg for 3 to 6 consecutive days. Pulse therapy usually is followed by high-dose prednisone (1 to 1.5 mg/kg per day) therapy that is tapered to low-dose maintenance therapy.37 Potential advantages of pulse therapy over high-dose oral steroids include a quicker response and avoidance of side effects associated with the longer duration of therapy required with oral steroids. Although generally well tolerated, methylprednisolone pulse therapy may result in significant adverse effects, including infection, gastrointestinal disturbances, rapid increases in blood pressure, arrhythmias, seizures, and sudden death. Furthermore, there are insufficient data from controlled clinical trials to clearly define the role of pulse steroids in the management of SLE. Thus pulse therapy represents an alternative mode of treatment for patients with life-threatening disease or disease unresponsive to other pharmacotherapy.

**Cytotoxic Drugs**

A considerable amount of literature exists describing the use of cytotoxic and immunosuppressive drugs in SLE, although few of these are reports of controlled clinical trials. Included in this category are the alkylating agent cyclophosphamide and the metabolite azathioprine. These agents, usually used in combination with corticosteroids, have been the mainstays of immunosuppressive therapy. Although both are known to suppress and stabilize extrarenal disease activity, much of the evaluation of these agents has focused on lupus nephritis, a major factor associated with morbidity and mortality in SLE.

Evidence supporting the use of cyclophosphamide in lupus nephritis has been collected over the last several decades. Controlled clinical trials have shown that cyclophosphamide improves long-term outcomes in lupus nephritis.1,38,39 Based on controlled trials, combination prednisone and cyclophosphamide has become standard treatment for focal and diffuse proliferative lupus nephritis (World Health Organization classes III/IV) and is superior to prednisone alone.38 No studies have evaluated cyclophosphamide in earlier stages of nephritis (World Health Organization classes II/III), and therefore, corticosteroids remain the treatment of choice for the initial treatment of nephritis.40 Pulse intravenous cyclophos-
phosphamide plus prednisone is more effective at slowing progression to end-stage renal disease than either prednisone alone or prednisone plus azathioprine.\textsuperscript{31} Cyclophosphamide plus corticosteroids, the current standard of care, decreases the risk of developing end-stage renal failure requiring dialysis and renal transplantation.\textsuperscript{42,43} Intermittent pulse administration of intravenous cyclophosphamide is preferred over daily oral therapies because of reduced adverse effects. However, pulse cyclophosphamide plus prednisone is not always effective.

When used in combination with corticosteroids, cyclophosphamide is dosed at 1 to 3 mg/kg for oral therapy and 0.5 to 1 g/m\textsuperscript{2} of body surface area for intravenous therapy. The most common route of cyclophosphamide administration is intravenous, although there is little evidence that this is better than oral administration.\textsuperscript{44} Likewise, there is no evidence to suggest the optimal duration of treatment. Based on empirical experience, cyclophosphamide generally is dosed monthly for 6 to 7 months and then every 3 months for a period of either 2 years or for 1 year after the nephritis is in remission.\textsuperscript{46} Of course, cyclophosphamide therapy is not without risk. Serious toxic effects include suppression of hematopoiesis, opportunistic infections, bladder complications (e.g., hemorrhagic cystitis and cancer), sterility, and teratogenesis. White blood cell counts must be monitored during cyclophosphamide therapy, and if the nadir is less than 1,500 cells/mm\textsuperscript{3} (1.5×10\textsuperscript{9}/L), the dose must be adjusted to keep the white cell count above 1,500 cells/mm\textsuperscript{3} (1.5×10\textsuperscript{9}/L).

Azathioprine can be used as a “steroid-sparing” agent, allowing for the reduction of corticosteroid dosages.\textsuperscript{29,42} Azathioprine has not been studied as extensively as cyclophosphamide for lupus nephritis. Data do not support the use of azathioprine as a part of an induction regimen; however, long-term maintenance azathioprine therapy may prevent renal flares after successful induction with cyclophosphamide.\textsuperscript{39,42} Azathioprine is given orally in doses of 1 to 3 mg/kg per day, often in combination with corticosteroids for severe disease. Azathioprine generally is less toxic than cyclophosphamide, but adverse reactions may be serious and include myelosuppression, opportunistic infections including herpes zoster, cancer, hepatotoxicity, and ovarian failure.

Cyclophosphamide often is administered intravenously in intermittent pulse doses to minimize toxicity. To decrease the risk of bladder toxicity, patients should be well hydrated with oral or intravenous fluids, and urinary output should be monitored. Mesna may be used to prevent hemorrhagic cystitis. Mesna is dosed at 20% of the total cyclophosphamide dose and is administered immediately before cyclophosphamide therapy and 3, 6, and 9 hours after therapy.\textsuperscript{45} Cyclophosphamide may be of benefit to some patients with other serious, refractory manifestations of lupus, including neurologic manifestations.\textsuperscript{46}

Because of the adverse effects of cyclophosphamide, other approaches to treating lupus nephritis have been attempted. Mycophenolate mofetil is an immunosuppressive agent that is effective treatment for severe renal and nonrenal lupus refractory to conventional cytotoxic agents.\textsuperscript{39,42} Mycophenolate mofetil has been investigated as an alternative to cyclophosphamide for induction of remission. In an open-label trial, mycophenolate mofetil was more effective than standard cyclophosphamide therapy, achieving a higher rate of complete and partial remissions.\textsuperscript{43} Prednisone was used in both treatment arms. Mycophenolate mofetil was also better tolerated. In this study, mycophenolate mofetil was initially dosed at 500 mg twice daily and was increased to 750 mg twice daily after 2 weeks; the dose continued to be increased weekly to a maximum of 1,000 mg three times daily. A larger study with longer follow-up is needed before any definitive conclusion can be drawn about the superiority of mycophenolate mofetil as induction therapy. Patients with the most severe forms of lupus nephritis should receive the standard boluses of intravenous cyclophosphamide plus corticosteroid therapy, but mycophenolate mofetil plus corticosteroid therapy may be a reasonable option for patients with mild to moderate nephritis and good renal function.\textsuperscript{48}

### CLINICAL CONTROVERSY

The use of intravenous cyclophosphamide for lupus nephritis as the standard of care is being questioned as newer data suggest that mycophenolate mofetil may be just as effective for induction and maintenance therapy.

Alternatives to cyclophosphamide for maintenance therapy also have been studied. Following induction therapy with the standard cyclophosphamide protocol, patients were assigned to either intravenous cyclophosphamide (0.5 to 1 g/m\textsuperscript{2} every 3 months), oral azathioprine (1 to 3 mg/kg per day) or oral mycophenolate mofetil (500 to 3,000 mg per day) with dose titrations. All groups received prednisone.\textsuperscript{49} This open-label study showed that standard cyclophosphamide induction followed by mycophenolate mofetil or azathioprine was more effective and better tolerated than standard cyclophosphamide bolus therapy. Although these data need to be interpreted cautiously because of study design limitations, azathioprine and mycophenolate mofetil are good options for maintenance therapy in lupus nephritis.\textsuperscript{50}

Cytotoxic therapy is useful in combination with corticosteroids, allowing for lower steroid doses and improved efficacy compared with steroids alone. However, cytotoxic therapy must be monitored closely for adverse effects, and maximum response may take 6 months or longer for some patients. Monitoring for adverse events, such as infection, myelosuppression, and long-term malignancies is essential.

### ALTERNATIVE AND EXPERIMENTAL TREATMENTS

As the pathogenesis of SLE continues to be elucidated, new and promising treatments are being developed. Many new therapeutic approaches are being studied in human clinical trials. Table 96–5 lists some agents currently available as well as new therapeutic agents in phase I, II, and III trials.\textsuperscript{47,51}

### SPECIAL POPULATIONS

#### Pregnancy

Pregnancy in SLE patients is associated with exacerbation of disease during pregnancy, exacerbation during the early postpartum

DHEA, dehydroepiandrosterone; LFA-1, lymphocyte function antigen-1.
period, a greater incidence of spontaneous abortion, and a greater chance of developing preeclampsia or pregnancy-induced hypertension (particularly for patients with nephritis).

Exacerbation of lupus during pregnancy seems to be less likely if the disease is in remission at conception.32,33 Disease exacerbations can be managed aggressively with corticosteroids, if needed, with little concern about harm to the fetus.33 The decision to use other classes of drug therapy to control disease exacerbation should be highly individualized, although hydroxychloroquine is safe during pregnancy.53,54 In fact, it may be safer to continue hydroxychloroquine during pregnancy than to discontinue it.53 The decision to use cytotoxic drugs during pregnancy should be made with extreme caution because of potential harmful effects (e.g., teratogenesis, fetal loss) to the fetus.55 Cyclosporine, methotrexate, and mycophenolate mofetil are contraindicated in pregnancy, but azathioprine can be used.55 NSAIDs are generally safe in pregnancy but should be discontinued during the last weeks of pregnancy due to risk of premature closure of the ductus arteriosus.

Antiphospholipid antibodies may be associated with a greater likelihood of spontaneous abortion.52,53 Corticosteroids, intravenous immunoglobulin, aspirin, and heparin, alone and in various combinations, have been used to try to improve fetal outcome.29 Fetal survival increases with all these therapies, but there is some controversy about their use alone or in combination.53,56 The optimal treatment regimen for pregnant patients with antiphospholipid antibodies is yet to be determined, although it has been recommended that women with antiphospholipid antibodies and no prior fetal losses should receive low-dose daily aspirin. High-risk women with a history of recurrent fetal loss should be treated with low-dose subcutaneous heparin with or without aspirin.52,53 Low-molecular-weight heparin may be an effective alternative to low-dose heparin in the treatment of antiphospholipid syndrome-related pregnancy loss.

Although there is an increased chance of a high-risk pregnancy in women with SLE, appropriate planning and disease management will result in a high likelihood of a successful pregnancy and a healthy child.

Contraception

Estrogen-containing oral contraceptives have been avoided for women with SLE because of the link between estrogens and disease activity. Uncontrolled trials suggest that oral contraceptives exacerbate SLE, but this issue was only recently rigorously examined. There are good reasons to prescribe oral contraceptives in SLE: (1) outcomes of pregnancy are better when pregnancies are planned and conception occurs during disease remission, (2) women with very active disease or receiving teratogenic medications should use a very reliable method of birth control, and (3) estrogen-containing oral contraceptives may have a beneficial effect counteracting glucocorticoid-induced osteoporosis.57

The use of a combined oral contraceptive (ethinyl estradiol plus levonorgestrel), a progestin-only contraceptive (levonorgestrel), and an intrauterine device were compared for women with SLE.58 This 12-month study showed comparable rates of disease flares and no clinically significant differences among all three groups during the trial. A placebo-controlled trial of ethinyl estradiol plus norethindrone also showed no difference in disease activity between the two groups over 12 months.59 Neither of these two trials studied combined oral contraceptives in severe active SLE, leaving the issue of oral contraceptives for these patients unanswered. Because of the risk of thrombotic events for estrogen-treated women and the risk of thrombosis in SLE, antiphospholipid antibodies should be measured before oral contraceptives are started, and oral contraceptives should probably be avoided if these antibodies are present.57

### Antiphospholipid Syndrome and Thrombosis

As mentioned earlier, the presence of antiphospholipid antibodies may result in several clinical manifestations, including thrombosis.26 There is no agreement on prophylaxis of patients with antiphospholipid antibodies without a history of thromboembolism.26 For such patients, low-dose aspirin (81 to 325 mg/day) may be used prophylactically, although efficacy is controversial.34 Patients with an acute thrombotic event should receive standard treatment with anticoagulants (e.g., heparin). Continued treatment with warfarin to prevent recurrence may require an international normalized ratio of 3 or greater for patients with antiphospholipid syndrome and recurrent thrombotic events.29,30 However, there is no consensus on the intensity of anticoagulation or duration of secondary prophylaxis, but as recurrence is common, patients are usually treated with oral anticoagulants indefinitely.59

#### Drug-Induced Lupus

Up to 10% of SLE cases may be drug-induced.60 More than 80 drugs have been implicated as causing drug-induced lupus (DIL), although the incidence for most of these drugs is low.60,61 Procainamide and hydralazine are associated most commonly with DIL (Table 96–6). A consensus on diagnostic criteria for DIL does not exist. To meet criteria for DIL, a patient should have exposure to a suspected drug, no prior history of idiopathic SLE prior to the use of the drug, development of ANAs (usually antihistone antibodies) and at least one clinical feature of SLE, and normal serum aminotransferase and alkaline phosphatase levels.

*Drugs in boldface represent those with best evidence of association. Data from references 60 to 64.*
rapid improvement of symptoms with a gradual decline in ANAs following drug discontinuation.\textsuperscript{60–62} The epidemiologic characteristics of DIL are different from those of idiopathic SLE. In general, patients with procainamide- or hydralazine-induced lupus develop the disease much later in life compared with idiopathic SLE probably because most people who use these drugs are older. There is also an absence of female predominance when compared with idiopathic SLE.

Patients of the slow acetylator phenotype may have a greater risk for developing DIL, particularly with procainamide and hydralazine.\textsuperscript{60} Procainamide-induced lupus can present as early as 1 month or even after years of therapy. Hydralazine-induced lupus is dose related, leading to the recommended maximum dose of 100 mg/day for men and 50 mg/day for women to minimize the risk of DIL.\textsuperscript{63}

Musculoskeletal symptoms are the most common clinical manifestations, while renal manifestations and CNS involvement are rare. Other common features of DIL include fever, fatigue, peri-carditis, pleurisy, and weight loss.\textsuperscript{64} The classic malar rash is rare in DIL, and skin manifestations are generally less frequent than idiopathic SLE.\textsuperscript{64} A positive ANA test is found in nearly all (>90%) hydralazine-induced cases and in 50% to 90% of procainamide-induced disease. The immunofluorescence pattern usually is homogeneous, and antibodies are primarily against ssDNA and not dsDNA as in idiopathic SLE. Antihistone antibodies are specific for DIL but might be found in only 20% of patients with idiopathic SLE.\textsuperscript{60}

If signs and symptoms of SLE appear in a patient and are suspected to be drug related, the drug should be discontinued. If the lupus is drug induced, the clinical manifestations should disappear in days to weeks, although it may take up to 1 year or longer for symptoms and serologic abnormalities to resolve completely.\textsuperscript{64} A NSAID might be useful in treating musculoskeletal manifestations. Other, more aggressive drug therapy should not be necessary unless manifestations are deemed more serious.

**PHARMACOECONOMIC CONSIDERATIONS**

Treating patients with SLE is costly, requiring frequent visits to physician offices for monitoring therapy and treating adverse reactions from therapy and hospitalization for disease exacerbation and adverse drug effects. Therefore, it is particularly important in the management of a potentially debilitating chronic disease such as SLE to achieve desired treatment outcomes in an optimal manner to minimize the impact on use of healthcare resources. Costs of treating patients with SLE are slightly higher in the United States compared with Canada and the United Kingdom, but outcomes are similar.\textsuperscript{65} The estimated mean annual direct cost in the United States ranges between $10,000 and $14,000 with mediations contributing approximately 26% of direct costs.\textsuperscript{66} Direct costs increase with more severe disease, longer disease duration, and worse mental and physical health status.\textsuperscript{66}

Disability from lupus also greatly impacts patients’ economic status. Indirect disease costs in terms of lost wages are high. In the first year following diagnosis the productivity cost is estimated at approximately $9,000.\textsuperscript{66} Work disability ranges from approximately 15% to 51% over 3 to 15 years following diagnosis.\textsuperscript{66}

**SYSTEMIC SCLEROSIS**

**CLINICAL MANIFESTATIONS**

Systemic sclerosis is characterized by alteration of the microvasculature and by massive deposition of collagen in the skin and internal organs. This disease can present as a spectrum of differing manifestations depending on affected areas and the extent of disease. Sclerosis of the skin is a hallmark for this disease, but other manifestations include a diffuse cutaneous (truncal) systemic sclerosis, with skin tightness and marked skin thickening involving most of the body. Internal organs can also be involved, such as the gastrointestinal tract, lung, kidney, or heart, and can result in death. "Scleroderma" refers to patients with only skin involvement. Disease that affects only the fingers and toes is referred to as "sclerodactyly."

**CLINICAL PRESENTATION OF SYSTEMIC SCLEROSIS**

- **General**
  - Sclerosis of the skin

- **Symptoms**
  - Raynaud’s phenomenon
  - Dyspepsia
  - Constipation
  - Diarrhea
  - Steatorrhea
  - Esophageal dysmotility

Most patients with systemic sclerosis (>95%) have Raynaud’s phenomenon, where the digits turn white, followed by a bluish color, which is then followed by reddening in response to an appropriate stimulus. The precipitating event is usually cold temperature or emotion. The pallor is caused by vasospasm, the bluish color is from ischemia, and the reddish color is caused by a reactive hyperemia. Raynaud’s phenomenon is a common manifestation of other syndromes, and most patients with Raynaud’s phenomenon do not have systemic sclerosis. Gastrointestinal symptoms related to dysphagia and gastroesophageal reflux disease or changes in bowel habits secondary to intestinal dysmotility are common particularly for patients with early disease. In recent years, the lung has emerged as a key target organ in systemic sclerosis. Over 90% of patients have evidence of interstitial lung disease upon autopsy, and 40% demonstrate restrictive changes via pulmonary function tests. Lung involvement is the leading cause of death, and survival is inversely related to the severity of restrictive lung disease.\textsuperscript{66,69}

**ETIOLOGY AND PREVALENCE**

The cause of systemic sclerosis is unknown. Ninety-five percent of patients have identifiable autoantibodies. There are two major subsets of the disease: limited cutaneous and diffuse systemic sclerosis. Patients with limited cutaneous involvement often have the Calcinosis, Raynaud’s phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasias (CREST) syndrome, whereas patients with diffuse systemic sclerosis have a more aggressive disease with renal, cardiac, or pulmonary involvement. The prevalence of the disease is estimated to be between 4 and 266 cases per 1 million persons.\textsuperscript{66,70,71} The wide range may be a result of differences in diagnostic criteria, regional variation, or sample sizes used to estimate the prevalence.
INFLAMMATORY MYOPATHIES

CLINICAL MANIFESTATIONS

The inflammatory myopathies are a heterogeneous group of relatively rare, chronic, inflammatory muscle diseases of unknown etiology. The major types of inflammatory myopathies are polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM). A fourth subtype, immune mediated necrotizing myopathy (NM), clinically resembles PM but has minimal inflammatory cell infiltrates on muscle biopsy. DM is distinguished from PM by a typical rash, which is red, scaly, and plaque-like, over the knuckles, wrists, elbows, and knees and typically precedes or accompanies the onset of muscle weakness. A blue-purple discoloration on the upper eyelids with edema also can occur in DM. Patients with inflammatory myopathies generally present with progressive weakness. In DM, PM, and NM the heart (pericarditis leading to heart failure or arrhythmia) and lungs (interstitial lung disease) may be affected, and patients may present with dysphagia and/or dyspnea. There is an increased risk of malignancy associated with PM, NM, and particularly DM.

An increased serum creatine kinase concentration and electromyography abnormalities are common. Other serum enzymes, such as the alanine transaminase, aspartate transaminase, and lactate dehydrogenase, also may be increased. Muscle biopsies show either characteristic inflammatory cell infiltrates (PM, DM, and IBM) or necrotic muscle fibers (NM). ANAs are detected in 24% to 60% of DM, 16% to 40% of PM, and up to 20% of IBM patients. Some patients develop certain "myositis specific antibodies" as well.

TREATMENT

Inflammatory Myopathies

DM, PM, and NM patients usually respond to immunotherapies, while IBM patients usually do not. A few small, randomized, double-blind, placebo-controlled trials evaluating the treatment of PM, DM, and IBM have been conducted, but evidence supporting use of drug therapy in large controlled trials is still lacking. It does appear that various immunotherapies may be helpful in both PM and DM. The goal of therapy is to increase muscle strength so as to improve function in activities of daily living (e.g., bathing, dressing, feeding, and toileting). Treatment consists of physical therapy during periods of remission and rest during periods of disease activity. Prednisone is the first line of drug therapy for PM and DM. Although the optimal dose of prednisone is not clear, most clinicians use prednisone at a starting dose of 60 to 100 mg/day or about 1 mg/kg per day as a single morning dose. Higher prednisone doses of 1.5 mg/kg per day can be used...
Polymyalgia Rheumatica (PMR) and Giant-Cell Arteritis

Polymyalgia rheumatica (PMR) and giant-cell arteritis (GCA) are closely related diseases, and some experts consider them to be different phases of the same disease.79,80 PMR is a disease characterized by severe bilateral pain and aching in the shoulders, neck, and pelvic girdles with associated morning stiffness. Systemic symptoms such as low-grade fever, fatigue, and weight loss are frequently present.81 GCA is a vasculitis of large- and medium-size vessels; it is the most common type of vasculitis in North America and Europe.82 The most frequent symptom of GCA is headache, with bilateral pain usually in the temporal or occipital areas; signs of systemic inflammation are also usually present.83,84 GCA was referred to previously as temporal arteritis or granulomatous arteritis. Both PMR and GCA occur in people older than 50 years of age, and the incidence increases with age, peaking between ages 70 and 80 years.82,84 Some patients go from exhibiting no symptoms to overt clinical manifestations overnight, whereas others have a gradual onset of symptoms over a number of weeks. The etiology is unknown.

TREATMENT

Polymyalgia Rheumatica and Giant-Cell Arteritis

The treatment of choice for both PMR and GCA is a corticosteroid, mainly prednisone.83,84 Several different dosing regimens have been studied, but a recent systematic review of PMR treatment studies published in the primary literature concluded that a starting dose of 15 mg/day of prednisone appears effective in most PMR patients and that once initial remission (control of symptoms) was achieved, the prednisone dose should be tapered slowly based on clinical symptoms and laboratory parameters [e.g., erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels]. Additionally, once a stable prednisone maintenance dose of 10 mg/day was achieved, further dose reductions should be smaller than 1 mg per month (e.g., 1 mg every 2 months). The authors also concluded that despite the differences in starting doses and tapering protocols studied, prednisone doses between 10 and 20 mg/day appeared to control symptoms at PMR onset and generally allowed for corticosteroid therapy discontinuation for about half of patients after 2 years of treatment.84 Usually the response to steroids is quite rapid, with complete or nearly complete symptom resolution within a few days. In fact, corticosteroid therapy is so effective that if improvement does not occur within a week, another diagnosis should be considered.87 The prednisone should be tapered beginning 2 to 4 weeks following control of symptoms. The rate of tapering is based on clinical response. A taper of 2.5 mg/day at 2- to 4-week intervals to 10 mg/day followed by a slower tapering of 1 mg/day at monthly intervals has been suggested.87,88 The lowest dose of prednisone that controls symptoms should be used for maintenance. Patients usually continue maintenance therapy for 1 to 3 years. Patients may experience a relapse when the prednisone is discontinued. For patients with GCA without visual or neurological symptoms but with systemic and inflammatory symptoms, daily prednisone doses of 40 to 60 mg (or 1 mg/kg/day) are generally used. Higher doses are recommended for patients with acute visual or neurological signs or symptoms (at least 80 mg/day or up to 2 mg/kg/day). In fact, it is common to hospitalize more acutely ill patients and start intravenous steroids such as methylprednisolone 250 mg every 6 hours for the first 3 to 5 days, then switch to high dose oral prednisone. High-dose prednisone is maintained for at least 4 to 6 weeks until systemic symptoms have diminished and laboratory markers of inflammation (ESR and CRP) have normalized. A slow taper should follow, and a maintenance dose of 7.5 to 10 mg/day is generally achieved in 6 to 12 months. Patients may require 1 to 5 years of steroid therapy.83 Because these are diseases of the elderly, it is particularly important to use calcium and vitamin D supplements to prevent corticosteroid-induced osteoporosis. Prophylactic bisphosphonate therapy also should be considered. Unlike most other autoimmune diseases, other forms of immunosuppressive therapy are not as effective as corticosteroids in PMR and GCA.85 However, there is evidence supporting methotrexate as a glucocorticoid-sparing agent when used to treat patients with

POLYMYALGIA RHEUMATICA AND GIANT-CELL ARTERITIS

CLINICAL MANIFESTATIONS

Polymyalgia rheumatica (PMR) and giant-cell arteritis (GCA) are closely related diseases, and some experts consider them to be different phases of the same disease.82,83

PMR is a disease characterized by severe bilateral pain and aching in the shoulders, neck, and pelvic girdles with associated morning stiffness. Systemic symptoms such as low-grade fever, fatigue, and weight loss are frequently present.84 GCA is a vasculitis of large- and medium-size vessels; it is the most common type of vasculitis in North America and Europe.85 The most frequent symptom of GCA is headache, with bilateral pain usually in the temporal or occipital areas; signs of systemic inflammation are also usually present.83,84,85 GCA was referred to
Instruments Used for Assessing Outcome Measures

Although there are no specific diagnostic tests for drug-induced vasculitis, but length of use varies widely in case reports. Most classes of medications have been reported to cause vasculitis. Although there are no specific diagnostic tests for drug-induced vasculitis, antineutrophil cytoplasmic autoantibodies have been identified in many cases of drug-induced vasculitis. ESR and CRP are often elevated in drug-induced vasculitides; anemia may be present as well. 

### CLINICAL PRESENTATION OF POLYMYALGIA RHEUMATICA AND GIANT-CELL ARTERITIS

**General**
- Aching and morning stiffness of neck, shoulder, and pelvic girdle musculature and torso.

**Symptoms**
- Pain and morning stiffness lasting 1 to 6 hours
- Fatigue, malaise, and weight loss usually present
- Anorexia
- Headache in GCA

**Signs**
- Low-grade fever

**Laboratory Tests**
- Erythrocyte sedimentation rate is generally >40 mm/h (11.1 μm/s) and often >100 mm/h (27.8 μm/s)

### DRUG-INDUCED VASCULITIS

**CLINICAL MANIFESTATIONS**

Drugs are common causes of vasculitis, often occurring in the skin, but other organ involvement (kidney and lung in particular) can occur. The pathogenesis of inflammation of blood vessel walls caused by drugs is poorly understood. Even drugs used to treat inflammatory and immune-mediated disease, such as NSAIDs, sulfasalazine, and etanercept, can cause vasculitis.

**CLINICAL PRESENTATION OF DRUG-INDUCED VASCULITIS**

**General**
- Signs and symptoms depend on organ involvement

**Symptoms**
- Rash
- Glomerulonephritis
- Hepatitis
- Fatigue
- Myalgia
- Arthralgia

**Signs**
- Fever

Long-term use of the offending agent is thought to be a risk factor for developing vasculitis, but length of use varies widely in case reports. Most classes of medications have been reported to cause vasculitis. Although there are no specific diagnostic tests for drug-induced vasculitis, antineutrophil cytoplasmic autoantibodies have been identified in many cases of drug-induced vasculitis. ESR and CRP are often elevated in drug-induced vasculitides; anemia may be present as well.

### EVALUATION OF THERAPEUTIC OUTCOMES

The diversity of clinical features and disease severity associated with the collagen-vascular diseases leads to a number of possible clinical outcomes with a broad range of desired therapeutic outcomes. Achieving desired therapeutic outcomes for most of the collagen-vascular diseases is highly variable. Currently, it is not possible to predict which patients will have a satisfactory therapeutic response and which will have unrelenting progressive disease. These diseases often have fluctuating courses, necessitating frequent changes in drug therapy and drug doses.

Evaluation of drug therapy of several of the collagen-vascular diseases often only requires monitoring for resolution of symptoms such as rash or muscle pain. However, patients with life-threatening disease receiving aggressive pharmacotherapy may require intensive monitoring and evaluation of therapy. For example, the patient receiving cytotoxic drug therapy for severe lupus nephritis requires close monitoring of laboratory indices of renal function, as well as monitoring of symptomatology and laboratory indices for possible bone marrow suppression, infection, cystitis, or other potential adverse effects.

Evaluation of therapeutic outcomes also should include an awareness of the possibility of drug therapy mimicking signs and symptoms of disease, such as the lupus patient receiving NSAID therapy and presenting with renal insufficiency or the patient with PM receiving prednisone and presenting with an exacerbation of muscle weakness.

As patients live longer, as is the case with SLE, outcome measures other than mortality will be needed to assess the effect of treatment. Clinicians and researchers working with lupus patients have developed and continue to refine some of these alternative outcome measures. Three important domains for assessing lupus patients are disease activity, accumulated damage, and quality of life. Table 96–7 lists several instruments useful for assessing patients with SLE.

Data from reference 91.
CONCLUSION

SLE is a disease that affects multiple organ systems and consists of abnormal immunologic function and the development of autoantibodies. The disease is quite variable in clinical presentation and progression. The cause of lupus is unknown, although several factors (e.g., genetics, environment, and hormones) may predispose an individual to the development of the disease. Although SLE was once thought to be rapidly fatal, today nearly 90% of patients survive 10 years.

Drug therapy is nonspecific and is aimed at suppressing the inflammation and abnormal immune response associated with active disease. Clinical trials with various agents often have been inadequate and contradictory, and the therapeutic management of lupus is not optimal. Nevertheless, drug therapy of recent years probably has contributed significantly to the improved survival of these patients. As the understanding of SLE progresses and advances in molecular biology occur, we can expect to see the development of more specific and optimal treatment and further improvement in survival.

Each of the collagen–vascular diseases has its own recommended form of therapy. For most of these diseases, there are few well-controlled clinical trials evaluating pharmacotherapy. Treatment of most of these diseases requires antiinflammatory or immunosuppressive drugs. Monitoring therapeutic outcomes is essential because drugs and drug doses may need to be modified frequently.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
ANA: antinuclear antibodies
CAD: coronary artery disease
CRP: C-reactive protein
DIL: drug-induced lupus
dM: dermatomyositis
DNA: deoxyribonucleic acid
dsDNA: double-stranded DNA
ESR: erythrocyte sedimentation rate
IVIG: intravenous immunoglobulin
NSAID: nonsteroidal antiinflammatory drug
PM: polymyositis
PMR: polymyalgia rheumatica
RNP: ribonucleoprotein
SLE: systemic lupus erythematosus
ssDNA: single-stranded DNA
RNA: ribonucleic acid

REFERENCES

KEY CONCEPTS

1. Hypersensitivity reactions are responsible for 6% to 10% of adverse reactions to medications. Although some reactions are relatively well defined, the majority are due to mechanisms that are either unknown or poorly understood.

2. The following criteria suggest that a drug reaction may be immunologically mediated: (a) the reaction occurs in a small percentage of patients receiving the drug, (b) the observed reaction does not resemble the drug’s pharmacologic effect, (c) the type of manifestation is similar to that seen with other allergic reactions (anaphylaxis, urticaria, serum sickness), (d) there is a lag time between first exposure of the drug and reaction, (e) the reaction is reproduced even by minute doses of the drug, (f) the reaction is reproduced by agents with similar chemical structures, (g) eosinophilia is present, or (h) the reaction resolves after the drug has been discontinued. Exceptions to each of these criteria are observed commonly.

3. Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that generally begins within 30 minutes but almost always within 2 hours after exposure to the inciting allergen. Anaphylaxis requires prompt treatment to restore respiratory and cardiovascular function. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilation. Intravenous fluids should be administered to restore intravascular volume.

4. Factors that influence the likelihood of allergic drug reactions are the chemical composition of the drug, whether the drug contains proteins of nonhuman origin, the route of drug administration, and the sensitivity of the individual as determined by genetics, or environmental factors. For some drugs, genetic predisposition to specific HLA alleles has been identified as a risk factor for allergic-mediated skin reactions.

5. Patients with a history of an immediate reaction to penicillin are advised not to receive cephalosporins if they can be avoided. Patients who have negative penicillin skin tests or experienced only mild cutaneous reactions, such as maculopapular rashes, have a low risk of serious reactions to cephalosporins.

6. Less than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction. Of the variety of reactions reported, approximately 90% are allergic like, mostly urticarial, with severe reactions occurring as infrequently as 0.02%.

7. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can produce two general types of reactions, urticaria/angiokerma and rhinosinusitis/asthma, in susceptible patients. About 20% of asthmatics are sensitive to aspirin and other NSAIDs.

8. Cross-reactivity between sulfonamide antibiotics and nonantibiotics is low. The low cross-reactive rate may be explained by differences in the chemical structures and reactive metabolites of the sulfonamide antibiotics and nonantibiotics.

9. The basic principles of management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.

10. One of the most helpful tests to evaluate risk of penicillin allergy is the skin test. Skin testing can demonstrate the presence of penicillin-specific immunoglobulin E and predict a relatively high risk of immediate hypersensitivity reactions. Skin testing does not predict the risk of delayed reactions or most dermatologic reactions.

11. Allergic drug reactions, also known as hypersensitivity reactions, result from an over-response of the immune system to the standard dose of a drug. The hyper-response of the immune system to the antigenic drug leads to host tissue damage manifesting as an organ-specific or generalized systemic reaction. Adverse drug effects not proven to be immune mediated but resembling allergic reactions in their clinical presentation are referred to as allergic-like or pseudoallergic reactions. Immunologically mediated adverse drug reactions account for 6% to 10% of all adverse drug reactions and even up to 15% by some estimates. Examples of allergic drug reactions are anaphylaxis from β-lactam antibiotics, halothane hepatitis, Stevens Johnson syndrome from sulfonamides, alopurinol hypersensitivity syndrome and serum sickness from phenytoin. Examples of pseudoallergic reactions are shock after radiocontrast media, aspirin-induced asthma, opiate-related urticaria, and flushing after vancomycin infusion.

The true frequency of allergic drug reactions is difficult to determine because many reactions may not be reported, and others may be difficult to distinguish from nonallergic adverse events. Dermatologic reactions represent the most frequently recognized and reported form of allergic drug reaction.
MECHANISMS OF ALLERGIC DRUG REACTIONS

Drugs can cause hypersensitivity reactions by a variety of immunologic mechanisms. Although some reactions are relatively well defined, most are due to mechanisms that are either unknown or poorly understood.2,3 The following criteria suggest that a drug reaction may be immunologically mediated: (a) the observed reaction does not resemble the drug’s pharmacologic effect, (b) there is a lag time between first exposure of the drug and reaction unless the recipient has been sensitized by prior exposure to the drug, which can lead to immediate reactions, (c) the reaction may occur even by minute doses of the drug, (d) the symptoms are characteristic of an allergic reaction (e.g., anaphylaxis, urticaria, serum sickness), (e) the reaction resolves after the drug has been discontinued, and (f) the reaction may be reproduced by agents with similar chemical structures.2 Exceptions to each of these criteria are observed commonly. Many allergic reactions can be classified into one of four immunopathologic categories: type I, II, III, or IV (Table 97–1 and Fig. 97–1).2,3

EFFECTORS OF ALLERGIC DRUG REACTIONS

Allergic drug reactions can involve most of the major components of the innate and adaptive immune systems, including the cellular elements, immunoglobulins, complement, and cytokines. Most immunoglobulin isotypes have been implicated in immunologically mediated drug reactions. Immunoglobulin E (IgE) bound to basophils or mast cells mediates immediate (anaphylactic-type) reactions. IgG or IgM antibodies also may be involved in allergic reactions, resulting in destruction of cells and tissues. T lymphocytes have a major role in hypersensitivity reactions and are involved in all four types (I–IV) of the drug hypersensitivity reactions described by Coombs and Gell.2,5,6

CELLULAR ELEMENTS

A variety of cells are involved in drug hypersensitivity. Antigen-presenting cells (APCs) include macrophages, dendritic cells, and cutaneous Langerhan cells. APCs process the antigenic drug for subsequent recognition by T and B lymphocytes. Basophils and mast cells are instrumental in the development of immediate hypersensitivity reactions, whereas eosinophils are recruited in both immediate and nonimmediate reactions. Platelets and vascular endothelial cells are important because they also can release a number of inflammatory mediators.2 Most cells of the body, including nerve cells, can become involved directly or indirectly in allergic drug reactions.

MEDIATORS OF ALLERGIC REACTIONS

The release of a number of preformed, pharmacologically active chemical mediators (e.g., histamine, heparin, proteases such as

![FIGURE 97-1. Types of hypersensitivity reactions.](image-url)
tryptase and chymase, and a variety of other enzymes) is triggered when antigens cross-link IgE molecules on the surface of circulating basophils and tissue mast cells. Newly formed mediators include platelet-activating factor and arachidonic acid metabolites (e.g., prostaglandins, thromboxanes, and leukotrienes).

Histamine is a low-molecular-weight amine compound formed by decarboxylation of histidine and is stored in basophil and mast cell granules. Release of histamine from these cells is triggered by antigen cross-linking IgE bound to specific receptors on the surface membranes of mast cells and basophils. The tissue effects of histamine are evident within 1 to 2 minutes, but it is rapidly metabolized within 10 to 15 minutes. The major effects of histamine on target tissues include increased capillary permeability, contraction of bronchial and vascular smooth muscle, and hypersecretion of mucus glands. Four classes of histamine receptors (H₁–H₄) are present to varying degrees in organs and tissues. H₁ receptors are most prominent in blood vessels and bronchial and intestinal smooth muscle.

Platelet-activating factor (PAF) is a glyceride-derived substance that is released by mast cells, alveolar macrophages, neutrophils, platelets, and other cells but not by basophils. It has potent bronchoconstrictor effects and causes platelet aggregation and lysis. It attracts neutrophils and causes their activation. PAF enhances vascular permeability and can cause pain, pruritus, and erythema.

The leukotrienes (LTs) are metabolites of arachidonic acid produced through the 5-lipoxygenase pathway that have potent effects on bronchial and vascular smooth muscle. Three important leukotrienes, LTC₄, LTD₄, and LTE₄, are produced by basophils or mast cells. These three substances are also referred to as cysteinyl leukotrienes and in older literature as slow-reacting substances of anaphylaxis. The LTs have more potent and longer-lasting bronchoconstrictor effects than histamine and can increase vascular permeability and cause arteriolar vasoconstriction followed by vasodilation. Their effects are slower in onset but longer lasting than those of histamine. Another product, LTB₄, is a potent chemoattractant, particularly for neutrophils. It is also produced by neutrophils, macrophages, and monocytes.

Prostaglandins (PGs) and thromboxanes are metabolites of arachidonic acid produced through the cyclooxygenase pathway. Some PGs have vasoconstrictive and/or bronchopulmonary properties, whereas others are vasodilatory and/or bronchoconstrictive. PGD₂ is the major PG product of mast cells. It is a potent inhibitor of platelet aggregation and is a bronchoconstrictor. Thromboxanes cause platelet aggregation and are important regulators of coagulation.

The complement system consists of approximately 30 plasma proteins and is involved in hypersensitivity through a variety of immunologic responses, including enhancement of phagocytosis (opsonization of target cells), cell lysis, and generation of anaphylatoxins (C₃a, C₄a, and C₅a), which can cause non-IgE-mediated activation of mast cells and release of inflammatory mediators.

**CLASSIFICATION OF IMMUNOPATHOLOGIC DRUG REACTIONS**

Immunologic mechanisms have been identified for some drug reactions, and many can be classified into one of four immunopathologic reactions, first described by Coombs and Gell. Small-molecular-weight molecules (<10 kDa) do not have the ability to serve as antigens on their own. With the exception of polypeptide compounds, most drugs are <1,000 Da. To become immunogenic, these small compounds must first covalently bind to carrier proteins in plasma or tissue. The combination of the drug bound to a carrier protein can be recognized as foreign by APCs and T lymphocytes, culminating in an immune response. The more likely that large amounts of the drug become chemically bound to a protein, the greater the risk of producing an allergic reaction. Penicillin G (356 Da) is an example of a drug that binds covalently to serum proteins through amide or disulfide linkages. For drugs such as the sulfonamides, the parent compound first must be converted to a metabolite before it can combine with the macromolecule. The species that combines with the carrier macromolecule is referred to as a hapten or an incomplete antigen. Some macromolecular drugs such as insulin are referred to as complete antigens because they are large enough to initiate an immune response without binding to another protein. Some small-molecular-weight drugs may cause an immune response through a non-hapten pathway. Known as the p-i concept, this pathway involves a pharmacologic interaction between the drug and the T-cell receptor that does not require the initial binding of the drug to a carrier protein or processing by APCs.

**TYPE I**

Type I reactions require the presence of IgE specific for the drug or the portion of the drug that becomes a hapten. IgE specific for the drug allergen is produced on initial exposure to the drug. It then binds to basophils and mast cells through high-affinity receptors. On repeat exposure to the drug, two or more IgE molecules on the basophil or mast cell surface may bind to one multivalent antigen molecule (referred to as cross-linking; see Fig. 97–1), initiating an activation of the cell. Activation causes the extracellular release of granules with preformed inflammatory mediators, including histamine, heparin, proteases (tryptase in the mast cell), as well as generation of newly formed mediators, as previously discussed, such as LTs, PGs, thromboxanes, and PAF, among others.

Generation of a type I reaction can be evident as an immediate hypersensitivity reaction, or anaphylaxis. Immediate reactions may be limited to single organs, typically in the nasal mucosa (rhinitis), respiratory tract (acute asthma), skin, or gastrointestinal tract, or they can involve multiple organs simultaneously, termed anaphylaxis.

**TYPE II**

Type II immunopathologic reactions involve destruction of host cells (usually blood cells) through cytotoxic antibodies by one of two mechanisms (see Fig. 97–1). First, the drug binds to the cell as a hapten (e.g., the platelet or red blood cell). Antibodies (IgG or IgM) specific for the bound drug or to a component of the cell surface that has been altered by the drug then bind, initiating a cytolytic reaction. Cell destruction may be mediated by complement or by phagocytic cells that have antibody Fc receptors on their surfaces. Activation of complement near the cell surface can result in loss of cell membrane integrity and cell death. Alternatively, neutrophils, monocytes, or macrophages may bind to an antibody-coated cell through IgG Fc receptors on their cell surfaces, resulting in phagocytosis of the target cell. The process of enhancement of phagocytosis by antibody binding to cell surfaces or other particles is referred to as opsonization. In addition, cell-bound IgG may direct the non-phagocytic action of T cells or natural killer cells, which results in cell destruction by a process called antibody-dependent cellular cytotoxicity. This process can proceed in a nonspecific fashion as T cells bind to the target cell through IgG Fc receptors on the T-cell surface. Contact between the target and effector cells is necessary.

Cells commonly affected by these types of reactions include erythrocytes, leukocytes, and platelets, resulting in hemolytic anemia, agranulocytosis, or thrombocytopenia, respectively. This process
may be initiated by drugs such as penicillin, quinidine, quinine, phenacetin, cephalosporins, and sulfonamides.

Another type of reaction that may affect the formed elements in blood is the "innocent bystander" reaction. With this type of reaction, antigen–antibody complexes formed in blood adhere nonspecifically to cells. Complement is then activated, resulting in cell lysis.

**TYPE III**

Type III immunologic reactions are caused by antigen–antibody complexes that are formed in blood. The complexes form with drug allergen and antibody in varying ratios and may deposit in tissues, resulting in local or disseminated inflammatory reactions. Antigen–antibody complex formation can result in platelet aggregation, complement activation, or macrophage activation. Chemotactic substances such as C5a also are produced. These substances cause the influx of neutrophils and result in the release of a number of toxic substances from the neutrophil (e.g., proteinases, collagenases, kinin-generating enzymes, and reactive oxygen and nitrogen substances), which can cause local tissue destruction.

Platelet aggregation may occur as a result of immune-complex formation, resulting in the formation of microthrombi and the release of vasoactive mediators. Also, insoluble complexes may be phagocytized by macrophages and activate these cells.

The formation of antigen–antibody complexes can lead to clinical syndromes such as the Arthus reaction. In this model, a high level of preformed specific IgG antibody combines with antigen to produce a localized edematous, erythematous reaction within 5 to 8 hours. The reaction involves local formation of insoluble antigen–antibody complexes, complement activation with release of C3a and C5a collectively referred to as *anaphylatoxins*, mast cell degranulation, and influx of polymorphonuclear cells.

**TYPE IV**

Type IV reactions are delayed hypersensitivity reactions that typically are demonstrated as dermatologic reactions mediated by T cells (CD4+ or CD8+). The Coombs and Gell classification of allergic drug reactions was developed prior to our understanding of the varied roles of T cells in the immune response. Four subclasses of type IV reactions (IVa–IVd) have been described. In this subclassification system, type IV reactions are differentiated based on the responding T cell (e.g., T helper type 1 cell, T helper type 2 cell, cytotoxic T cell), effector mechanism (e.g., recruitment of macrophages, eosinophils, or neutrophils) and clinical manifestations (e.g., contact dermatitis, bullous exanthems, maculopapular eruptions, purpural exanthems). Type IV reactions require memory T cells specific for the antigen in question. On exposure to the antigen, the immune response is mediated by a specific subtype of T cell that orchestrates an inflammatory response through the secretion of cytokines and the recruitment of effector cells. These reactions are associated with a wide variety of adverse effects (e.g., contact dermatitis, maculopapular exanthemas, bullous exanthemas, eczema, or purpural exanthemas), and they also may be useful for diagnostic purposes. Examples of the latter include the purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis* used in the tuberculin skin test and other recall skin test antigens, such as mumps. After intradermal injection, these antigens produce a local reaction (erythema and induration) within 48 to 72 hours. Delayed contact hypersensitivity also can be caused by a wide variety of chemicals and drugs.

**OTHER ALLERGIC REACTIONS**

The precise mechanism of many drug reactions is not known, although the reactions are believed to be immune mediated. Perhaps most common are the delayed dermatologic reactions that occur with a variety of drugs (especially penicillins and sulfonamides). These reactions may be evident as fixed drug eruptions, macropapular, morbilliform, or erythematous rashes; exfoliative dermatitis; photosensitivity reactions; or eczema. These reactions also may be manifest as late onset pruritis, urticaria, and angioedema.

A number of serious cutaneous adverse reactions, known as SCARs, may be the result of immunologic reactions. SCARs include drug rash with eosinophilia and systemic symptoms (DRESS) and the mucocutaneous disorders, Stevens Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). Drug-induced fever also may involve immunologic mechanisms. Other general types of reactions believed to be immune mediated in some cases include hepatic drug reactions (cholestatic or hepatocellular) and pulmonary reactions, for example, interstitial pneumonitis, which has been associated with nitrofurantoin.

**ANAPHYLACTOID REACTIONS**

Various drugs and other substances can produce anaphylactoid (anaphylaxis-like) reactions that are similar to anaphylaxis in clinical signs and symptoms. The substances causing these reactions can lead to the direct release or activation of inflammatory mediators from cells by a pharmacologic or physical effect rather than through cell-bound IgE. These reactions are the most severe form of pseudoallergy, but not all pseudoallergic reactions are anaphylactoid. Pseudoallergy refers to a wide array of reactions ranging from localized hives to life-threatening angioedema, hypotension, and anaphylaxis, all of which are explained by the nonimmunologic release or activation of inflammatory mediators. Drugs that can produce anaphylactoid reactions include vancomycin, opiates, iodinated radiocontrast agents, angiotensin-converting enzyme inhibitors, amphotericin B, and D-tubocurarine. The "red man syndrome" is a common example of a pseudoallergic reaction from vancomycin. If vancomycin is infused too rapidly, it can cause the direct release of histamine and other mediators from cutaneous mast cells, producing a typical clinical picture of itching, flushing, and hives, first around the neck and face and then progressing to the chest and other parts of the body usually beginning shortly after the infusion has begun. In some cases, the cutaneous manifestations of "red man syndrome" may be accompanied by hypotension, thereby constituting an anaphylactoid event. Most patients who have had "red man syndrome" will tolerate vancomycin if the rate of infusion is slowed. In rare cases, the severity of the reaction may preclude continued therapy with vancomycin. A number of other agents (including aspirin) may produce anaphylactoid reactions by altering the metabolism of inflammatory mediators such as PGs or kinins. Angioedema from angiotensin-converting enzyme inhibitors is a classic example of an anaphylactoid reaction. Although the mechanism by which this anaphylactic-like event occurs is not fully understood, inhibition of the breakdown of bradykinin and substance P by the angiotensin-converting enzyme inhibitor may explain the inflammation, increased vascular permeability and vasodilation.

**CLINICAL MANIFESTATIONS OF ALLERGIC AND ALLERGIC-LIKE REACTIONS**

**ANAPHYLAXIS**

Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that occurs in 10 to 20 per 100,000 population per year. Approximately 1,500 deaths from anaphylaxis occur annually in the United States. From 1.2% to 15% of the U.S. population may be at risk for anaphylactic reactions.
Although many drugs may cause anaphylaxis (or anaphylactoid) reactions, the most commonly reported are penicillins, aspirin and other NSAIDs, and insulins. In most patients, the initial signs and symptoms are referable to the skin (flushing, pruritus, urticaria, angioedema). The second most common symptoms are respiratory (tightness of the throat and chest, dyspnea, dysphonia and hoarseness, cough, stridor, shortness of breath, dyspnea, congestion, rhinorrhea, sneezing) followed by dizziness and gastrointestinal tract symptoms (nausea, crampy abdominal pain, vomiting, diarrhea). Ten percent to 30% of patients develop hypotension. Additional cardiovascular effects include syncope, altered mental status, chest pain, and dysrhythmia. A consensus panel has constructed a definition of anaphylaxis as follows. Anaphylaxis is highly likely when any one of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, pruritus or flushing, swollen lips/tongue/uvula) AND at least one of the following:
   - Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced peak expiratory flow, hypoxemia)
   - Reduced blood pressure or associated symptoms of end-organ dysfunction (e.g., hypotonia, syncope, incontinence)

2. Two or more of the following that occur rapidly after exposure to a likely allergen (minutes to several hours):
   - Involvement of skin/mucosal tissue (as above)
   - Respiratory compromise (as above)
   - Reduced blood pressure or associated symptoms
   - Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)

3. Reduced blood pressure after exposure to known allergen (minutes to several hours)

The panel indicated that other presentations may indicate anaphylaxis and that the potential exists for false-positive results.

Anaphylactic reactions generally begin within 30 minutes but almost always within 2 hours of exposure to the inciting allergen. The risk of fatal anaphylaxis is greatest within the first few hours. After apparent recovery, anaphylaxis may recur 6 to 8 hours after antigen exposure. Because of the possibility of these “late-phase” reactions, patients should be observed for at least 12 hours after an anaphylactic reaction. Fatal anaphylaxis most often results from asphyxia due to airway obstruction either at the larynx or within the lungs. Cardiovascular collapse may occur as a result of asphyxia in some cases, whereas in others cases cardiovascular collapse may be the dominant manifestation from the release of mediators within the heart muscles and coronary blood vessels.

**SERUM SICKNESS AND SERUM SICKNESS-LIKE DISEASE**

Serum sickness is a clinical syndrome resulting from the effects of soluble circulating immune complexes that form under conditions of antigen excess. The reaction commonly results from the use of antisera containing foreign (donor) antigens such as equine serum in the form of antitoxins or antivenoms. The onset of serum sickness is usually 7 to 14 days after antigen administration. The onset may be more rapid with reexposure to the same agent in an individual with prior serum sickness. Fever, malaise, and lymphadenopathy are the most common clinical manifestations. Arthralgias, urticaria, and morbilliform skin eruption also may be present. A milder and more transient form of serum sickness is serum sickness-like disease (SSLD). The predominant feature of SSLD is a cutaneous eruption, either urticarial or maculopapular, that occurs within 5 to 21 days of drug administration. As with serum sickness, the rash is usually preceded by a prodromal phase consisting of fever, malaise, lymphadenopathy, and arthralgias. SSLD has been associated with the administration of ciprofloxacin, bupropion, hydantoins, minocycline, sulfonamides, penicillins, and cephalosporins (especially cefaclor). SSLD is usually self-limiting after discontinuation of the causative agent, but it can sometimes progress to include vasculitis.

**DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)**

Previously known by the term drug hypersensitivity syndrome, the triad of rash, eosinophilia and internal organ involvement is currently referred to as drug rash with eosinophilia and systemic symptoms (DRESS). Bocquet and colleagues described the following criteria for a diagnosis of DRESS: (1) cutaneous drug eruption (usually a diffuse maculopapular rash accompanied by facial and neck edema); (2) hematologic abnormalities including eosinophilia greater than 1,500 cells/mm$^3$ $(1.5 \times 10^9/L)$ or the presence of atypical lymphocytes; and (3) systemic involvement including adenopathies greater than 2 cm in diameter, hepatitis, interstitial nephritis, interstitial pneumonia or carditis. Both the allopurinol hypersensitivity syndrome and anticonvulsant hypersensitivity syndrome are examples of DRESS. Other drugs associated with DRESS include minocycline, dapsone, lamotrigine and the sulfonamides. The onset of DRESS is typically delayed ranging from 3 to 8 weeks after drug initiation, and there is a high degree of interpatient variability in the targeted organs and the severity of organ involvement. The mortality rate associated with DRESS is 10% and it is largely attributed to systemic involvement of the liver, kidneys, or lungs. Following discontinuation of the causative drug, the skin rash resolves and laboratory abnormalities normalize over a period of 4 to 8 weeks. Systemic corticosteroids (0.5–1 mg/kg/day prednisone or steroid equivalent) have been used in the treatment of DRESS based on the severity of organ involvement.

**DRUG FEVER**

Fever may occur in response to an inflammatory process or develop as a manifestation of a drug reaction. Drug fever occurs in as many as 10% of hospital inpatients. Many drugs have been reported to cause fever, including acyclovir, heparin, methyldopa, procainamide, phenytoin, barbiturates, quinidine, and a variety of antibiotics (e.g., β-lactams, rifampin, sulfonamides, tetracycline, vancomycin). These drugs may affect the central nervous system directly to alter temperature regulation or stimulate the release of endogenous pyrogens (e.g., interleukin 1 and tumor necrosis factor) from white blood cells. Drugs also may cause fever as a result of their pharmacologic effects on tissues, for example, fever resulting from massive tumor cell destruction caused by chemotherapy. However, the mechanism of drug fever remains unknown for agents such as amphotericin B and radiographic contrast agents.

The temperature pattern of drug-induced fever is quite variable and therefore of little help in the diagnosis. It may be low grade and continuous or spiking and intermittent. A temporal relationship between drug administration and occurrence of fever has been noted for some medications. Generally, withdrawal of the causative agent results in prompt defervescence as soon as the drug is eliminated completely. Fever usually recurs on readministration of the causative agent.
**DRUG-INDUCED AUTOIMMUNITY**

Autoimmune diseases have been associated with drugs and may involve a variety of tissues and organs. A commonly recognized drug-related autoimmune disorder is systemic lupus erythematosus (SLE) induced by infliximab, etanercept, procainamide, hydralazine, quinidine, or isoniazid. Exposure of susceptible persons to these agents appears to alter normal body proteins, RNA, or DNA in such a way as to make these components antigenic, leading to the formation of autoreactive antibodies and cells. Most patients treated with infliximab develop antinuclear antibodies, but only 2% of patients present with SLE symptoms. The most common clinical manifestations include arthralgias, myalgias, and polyarthropathy. Facial rash, ulcers, and alopecia occur less frequently. Renal or pulmonary involvement typically also may occur. These reactions typically develop several months after beginning the drug and generally resolve soon after the drug is discontinued.

Other syndromes believed to involve autoimmune mechanisms include drug-induced hemolytic anemia attributed to methyldopa, interstitial nephritis produced by methicillin, and hepatitis caused by phenytoin and halothane. Interstitial nephritis is characterized by fever, rash, and eosinophilia associated with proteinuria and hematuria. Hepatic damage due to drugs generally is manifested as either hepatocellular necrosis or cholestatic hepatitis. Drug-induced hepatitis has been associated with phenothiazines, sulfonamides, halothane, phenytoin, and isoniazid (see Chapter 45). Hepatocellular destruction is evidenced by elevations in serum transaminases. Hepatomegaly and jaundice sometimes may be evident. Cholestatic may be manifested by jaundice and elevations in serum alkaline phosphatase and sometimes by rash, fever, and eosinophilia.

**VASCULITIS**

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessel walls. The vasculitic process may be limited to the skin, or it may involve multiple organs, including the liver or kidney, joints, or central nervous system. Characteristically, cutaneous vasculitis is manifested by purpuric lesions that vary in size and number. Vasculitis also may be manifested as papules, nodules, ulcerations, or vesiculobullous lesions, generally occurring on the lower extremities but sometimes involving the upper extremities, including the hands. Drugs associated with vasculitis include allopurinol, β-lactam antibiotics, sulfonamides, thiazide diuretics, phenytoin, and vancomycin.

**DERMATOLOGIC REACTIONS**

A wide variety of dermatologic drug reactions have been reported to have an immunologic basis. Cutaneous reactions are the most common manifestations of allergic drug reactions. Although most dermatologic reactions are mild and resolve promptly after discontinuing the drug, some such as SJS and TEN are serious or even life-threatening reactions. Both SJS and TEN are classified as progressive bullous or “blistering” disorders that constitute dermatologic emergencies. They are considered severe variants of erythema multiforme. Similar to erythema multiforme, SJS and TEN are associated with widespread development of a variety of skin lesions including macules, purpuric lesions and the target iris lesion. The target lesion is discrete, round, and identified by an area of central clearing surrounded by two concentric rings of edema and erythema. Unlike erythema multiforme, SJS and TEN are most commonly drug-induced rather than associated with recurrent herpes simplex viral infection, and they progress to include mucous membrane erosion and epidermal detachment. Mucosal membranes in the mouth, lips, nasal cavity, and conjunctivae are usually involved. As these syndromes progress, the eratomatous lesions become more widespread on the face, trunk, and extremities, and many evolve into blisters. Within days after the onset of the lesions, full-thickness epidermal detachment occurs. SJS and TEN are often considered as a continuous spectrum of a disease, with TEN being the most severe form. The extent of epidermal detachment is used to distinguish between SJS and TEN (i.e., <10% detachment of body surface area with SJS; >30% detachment of body surface area with TEN). The term SJS-TEN overlap is used to describe cases in which epidermal detachment occurs on 10% to 30% of the body surface area. Both SJS and TEN are associated with a number of long-term sequelae including permanent visual impairment, temporary nail loss, cutaneous scarring and irregular pigmentation. Being the more severe form, TEN is also more likely to be complicated by systemic organ involvement including acute kidney failure, neutropenia, and respiratory failure. A severity-of-illness scoring system known as SCORTEN has been developed to predict prognosis in patients with TEN. SCORTEN uses seven independent risk factors based on an assessment within 24 hours of clinical presentation.

Cutaneous adverse reactions were reported to occur in 2.7% of hospitalized patients. TEN is estimated to occur in 0.4 to 1.3 cases per 1 million people per year while SJS has been reported in 1 to 6 cases per 1 million people per year. The mortality rates associated with SJS and TEN range from 1% to 5% and 10% to 70%, respectively. Table 97–2 lists drugs and agents associated most commonly with cutaneous reactions. In general, antimicrobials are implicated most frequently as the cause of cutaneous events with reaction rates ranging from 1% to 8%. The most likely offenders of SJS and TEN, determined in case-control studies, are the sulfonamides, particularly trimethoprim-sulfamethoxazole. Other major offenders of SJS and TEN identified in these studies are allopurinol, the aminopenicillins, carbamazepine, chloromezanone, cephalosporins, the imidazole antifungals, lamotrigine, nevirapine, the oxim NSAIDs, phenytoin, quinolones, and the tetracyclines.

**RESPIRATORY REACTIONS**

Drugs may produce upper or lower respiratory tract reactions, including rhinitis and asthma. Respiratory tract manifestations may result from direct injury to the airways or may occur as a component of a systemic reaction (e.g., anaphylaxis). Asthma may be induced by aspirin and other NSAIDs or by sulfites used as preservatives in foods and medications. Other pulmonary drug reactions believed to be immunologic include acute infiltrative and chronic fibrotic pulmonary reactions. The latter is often caused by anti-neoplastic agents such as bleomycin. For a more detailed discussion of drug-induced pulmonary disease, see Chapter 36.

HEMATOLOGIC REACTIONS

Most formed elements and soluble components of the hematopoietic system may be affected by immunologic drug reactions. Eosinophilia is a common manifestation of drug hypersensitivity and may be the only presenting sign. Hemolytic anemia may result from hypersensitivity to drugs. Other hematologic reactions include thrombocytopenia, granulocytopenia, and agranulocytosis. For a detailed discussion of hematologic drug reactions, see Chapter 112.

FACTORS RELATED TO THE OCCURRENCE OR SEVERITY OF ALLERGIC DRUG REACTIONS

Among the factors that influence the likelihood of allergic drug reactions are the degree to which the drug and its metabolites bind covalently to human proteins, how the drug is metabolized, whether the drug contains proteins of nonhuman origin (e.g., chimeric monoclonal antibodies, streptokinase) or antigenic excipients (e.g., peanut oil, FD&C dyes, sulfites, soybean emulsion), the route of exposure, and the sensitivity of the individual as determined by genetics, and environmental factors. Hypersensitivity can occur with any dose of a drug, but sensitization is more likely to occur with continuous dosing rather than single dosing. Once a patient has become sensitized, the severity of a reaction is often determined by the dose and the duration of exposure. The route of administration may also influence drug sensitivity. The topical route of drug administration appears to be the most likely to sensitize and predispose to drug reactions. The oral route is the safest, and the parenteral route is the most hazardous for administration of drugs in sensitive individuals. Relatively few cases of immediate hypersensitivity-associated deaths with oral β-lactam antimicrobials have been reported.

Individual host factors are important in determining drug sensitivity. A genetic predisposition for some types of allergic reactions has been identified. The presence of genetically determined human leukocytic antigen (HLA) alleles increases susceptibility to a number of drug hypersensitivity syndromes. In patients infected with the human immunodeficiency virus (HIV), hypersensitivity to abacavir has been associated with the presence of HLA-B*5701. Severe immune-mediated cutaneous reactions to allopurinol including SJS and TEN have been associated with the presence of HLA-B*5801 in Han Chinese. In this same patient population, the presence of HLA-B*1502 increases the risk of SJS and TEN with carbamazepine, phenytoin and fosphenytoin. Genetic factors can also influence the metabolic deactivation of drugs via phase 1 and 2 metabolism. For example, slow acetylators of procainamide and hydralazine are at increased risk for SLE. Genes also encode for the type of T cell receptor and the specific cytokines involved in the signaling of allergic drug reactions.

Drug allergies appear to develop with equal frequency in atopic and nonatopic individuals. In addition, patients with a history of drug allergy appear to be at increased risk for adverse reactions to other pharmacologic agents. Age seems to be related to the risk of allergic reactions, as they occur less frequently in children. This may be related to immaturity of the immune system or decreased exposure. The presence of some concurrent diseases, particularly viral infections, predisposes to drug reactions. Examples include the higher rate of morbilliform rash when ampicillin is administered to patients with infectious mononucleosis, the higher rate of reactions to trimethoprim-sulfamethoxazole in HIV-infected patients and the relationship between infection with human herpes-virus 6 (HHV-6) and the development of drug rash with eosinophilia and systemic symptoms (DRESS).

DRUGS COMMONLY CAUSING ALLERGIC OR ALLERGIC-LIKE DRUG REACTIONS

β-LACTAM ANTIMICROBIALS

Allergy to β-lactam antibiotics is commonly reported by patients in healthcare settings. Allergic reactions to penicillin occur in 0.7% to 8% of treatment courses but was as high as 15% in one retrospective report of hospitalized patients treated with penicillin. Although most patients reporting penicillin allergy do not have allergy, a reported history is associated with a higher likelihood of positive skin test reactivity. Only 10% to 20% of patients reporting penicillin allergy are found to be allergic by skin testing. Patients with a history of immediate penicillin allergy who have a negative penicillin skin test are unlikely to react on subsequent courses of penicillin.

The most common reactions to penicillin include urticaria, pruritus, and angioedema. All four of the major types of hypersensitivity reactions have been reported with penicillin, as well as some reactions that do not fit into these categories. A wide variety of idiosyncratic reactions occur, such as maculopapular eruptions, eosinophilia, SJS, and exfoliative dermatitis. Cutaneous reactions can occur in up to 4.4% of treatment courses of penicillin and in up to 8% with aminopenicillins. The incidence of ampicillin rash is close to 100% in patients with viral infections such as infectious mononucleosis.

Some aspects of the mechanism of penicillin immunogenicity have been determined. Because benzylpenicillin is a relatively small molecule (356 Da), it must combine with macromolecules (presumably proteins) to elicit an immune response. Penicillin is rapidly hydrolyzed to a number of reactive metabolites that have the ability to covalently link to proteins. Of these metabolites, 95% is in the form of benzylpenicilloyl that binds covalently to the lysine residues of proteins such as albumin through an amide linkage involving the β-lactam ring (Fig. 97–2). This penicilloyl–protein conjugate is referred to as the major antigenic determinant. The other penicillin metabolites such as penilloate and penicilloate bind in lesser quantities to proteins. These are referred to as minor antigenic determinants. The terms major and minor refer to the relative proportions of these conjugates that are formed and not to the clinical severity of the reactions generated. Immediate hypersensitivity reactions may be mediated by IgE for both minor and major determinants. In fact, the minor antigenic determinants are more likely to cause life-threatening anaphylactic reactions.

In addition to the major and minor determinants, unique side chain determinants may mediate allergy to some penicillins. Both the aminopenicillins and piperacillin may cause hypersensitivity reactions via unique side chains on their structures. Therefore, a patient may exhibit hypersensitivity to amoxicillin or piperacillin via a side chain determinant while exhibiting no reactivity to other penicillins. Careful history taking is needed to identify patients with high likelihood of side-chain specific reactions. Skin testing with dilute concentrations of amoxicillin, ampicillin, and piperacillin has been used to aid in the determination of side-chain specific reactions.

Patients who are allergic to penicillins also may be sensitive to other β-lactams. The exact incidence of cross-reactivity between cephalosporins and penicillins is not known but is believed to be low. The risk was originally reported as 10% to 15% in the 1970s when cephalosporins were contaminated with trace amounts of penicillin. Current estimates of the cross-reactive risk between penicillin and the first- and second-generation cephalosporins are 5% to 7.5% and as low as 1% between penicillin and the third- and fourth-generation cephalosporins. One percent to 8% of patients...
with penicillin-specific IgE may develop an immediate-type hypersensitivity reaction to cephalosporins. In contrast, patients with reported penicillin allergy and negative skin test are at no greater risk.

Cephalosporins should be avoided in patients with a history of hives or other immediate hypersensitivity reactions from penicillin, although some studies have suggested there is little risk of an allergic response to a cephalosporin even in a person with a positive skin test to penicillin. Based on the results of one meta-analysis, patients with penicillin allergy have the highest risk of cross-reactivity with the first generation cephalosporins (odds ratio [OR], 4.79; 95% confidence interval [CI], 3.71–6.17). The odds of reacting to a second- and third-generation cephalosporin were 1.13 (95% CI, 0.61–2.12) and 0.45 (95% CI, 0.18–1.13), respectively. The higher rate of cross-reactivity between penicillin and the first generation cephalosporins has been attributed to similarities in the R1 side chains of these agents. The R1 side chain is connected to the opened β-lactam ring, thereby influencing the antigenicity of these agents. When assessing the potential for cross-reactivity between penicillins and cephalosporins, clinicians should evaluate the similarities in the R1 side chains of the agents. Table 97–3 provides a list of penicillins and cephalosporins having similar side chains in the R1 position.

Cephalosporins can induce immune responses mediated by the core β-lactam structure or via unique side chain determinants. In a patient with a cephalosporin allergy, skin testing with the major and minor determinants of penicillin can be used to identify the likelihood of reactivity to the core β-lactam ring. The risk of cross-reactivity between cephalosporins is considered to be higher than that between the penicillins and cephalosporins. Cross-reactions may occur through identical R1 side chains. Of note, ceftazidime shares a common side chain with aztreonam.

The actual risk of a cross-reaction between the penicillins and the carbapenems appears to be much lower than originally described. The initial estimate of the cross-reactive risk was 47.4%, but current estimates range from 0.9% to 11%. The initial estimate was based on the results of skin testing with penicillin and nonstandardized carbapenem reagents. A number of retrospective studies reporting variable rates of cross-reactivity relied on self-reported histories as confirmation of penicillin allergy. Three recently published prospective studies used both skin testing methods and carbapenem challenge dosing to assess cross-reactive risk. In one of these studies, only 1 of 112 patients with skin test-confirmed penicillin allergy demonstrated a positive skin test to imipenem. Challenge dosing with imipenem to a final dose of 500 mg was subsequently performed in 110 patients with negative imipenem skin tests; none of the 110 patients had a reaction. Results of two additional prospective studies, one of which was performed in children ages 3 to 14 years, suggest a low risk of cross-reactivity between penicillin and meropenem. In both studies, only one patient with skin-test positivity to penicillin had a positive skin test to meropenem. Graded challenge dosing with meropenem was tolerated in 100% of the skin-test negative patients in both

studies. It is important to note that none of the skin-test negative patients were subsequently treated with full therapeutic regimens of the carbapenem. However, the high level of tolerability to challenge dosing suggests a low rate of cross-reactivity in skin-test negative patients. Based on these results, the routine practice of avoiding carbapenem use in patients with history of penicillin allergy should be reconsidered.47

Of the monobactams, aztreonam only weakly cross-reacts with penicillin and can be administered safely to most patients who are penicillin allergic.47

RADIOCONTRAST MEDIA

Radiocontrast agents frequently cause reactions categorized as immediate (in ≤1 hour) or non-immediate (1–10 days) via both IgE-mediated and non-IgE-mediated mechanisms.55 The frequency and severity of these reactions are influenced by the type of radiocontrast agent (ionic versus nonionic), and patient-specific factors such as history of atopy, asthma, or prior reaction to a radiocontrast agent. From <1% to >3% of patients receiving nonionic contrast media experienced an adverse reaction, with reports as high as 12.7% for mild reactions.55,56 Delayed skin reactions, usually presenting as maculopapular exanthems, occur in 1% to 3% of patients over 5 to 7 days. Severe, immediate anaphylactic reactions occur in 0.01% to 0.04% of patients.59 In addition, radiocontrast agents may cause dose-dependent toxic reactions that can produce renal impairment, cardiovascular effects, and arrhythmias.57 The older, high-osmolar ionic agents that are now used less commonly have a greater frequency of reactions compared with the newer, low-osmolar agents.58 The mechanism of reactions to radiocontrast agents is not clearly understood. Histamine release and mast cell triggering have been documented in severe immediate reactions, suggesting an IgE-mediated mechanism.58 The older, high-osmolar radiocontrast agents can activate mast cells, basophils and the complement system directly (IgE-independent mechanism), resulting in the release of inflammatory mediators. The delayed-onset maculopapular rash appears to be T-cell mediated. The low-osmolar nonionic contrast agents appear to cause fewer anaphylactoid reactions.

The risk of anaphylactoid reactions to radiocontrast media is greater in women and in patients with a history of atopy or asthma.55 Other recognized risk factors include a history of previous reaction, severe drug allergies, cardiac disease, and treatment with β-blockers.55 Despite a common misconception, seafood allergy or iodine allergy does not predispose to radiocontrast media reactions. Neither skin tests nor oral tests are useful for predicting reactions to these agents. Although some regimens have been recommended to prevent the recurrence of immediate events in patients who have experienced reactions previously, the value of these preventive regimens has not been proven and their use remains controversial.53,55,58 A commonly recommended regimen in high risk patients is oral prednisone (50 mg) 13, 17, and 1 hours before exposure with 50 mg of diphenhydramine given orally or intramuscularly 1 hour before exposure to prevent immediate reactions.65 Ephedrine 25 mg orally has also been recommended 1 hour before the radiocontrast study as a component of the pretreatment regimen; however, ephedrine should not be used if the patient has history of unstable angina, hypertension or arrhythmia.65 Other studies have examined the use of H1- and H2- antihistamines, clemastine, or cimetidine, respectively.59

INSULIN

Insulin is capable of producing allergic reactions through a variety of immunologic mechanisms. A protein molecule, insulin is a complete antigen. Allergic reactions have been reported with beef, pork, and recombinant human insulin, although the frequency of reactions with human insulin appears low. Reactions to insulin may involve the insulin molecule itself or other substances that have been added to insulin (e.g., protamine). Most patients have anti-insulin IgG antibodies after a few months of therapy.

Insulin reactions may be limited to the site of injection, or they may produce systemic reactions. Local reactions present most often as a wheal and flare at the injection site and may occur immediately after injection or up to 8 to 12 hours later. Generally, these reactions are mild, do not require treatment, and resolve with continued insulin administration. If a patient does not tolerate the local reaction well, antihistamines may be given or a different insulin source (or product of higher purity) may be substituted. Rarely, systemic reactions to insulin (e.g., urticaria or anaphylaxis) occur. IgE-mediated reactions to insulin allergy appear to be declining with greater use of human insulins.61 Skin testing with various products can aid in selecting the type of insulin least likely to cause a systemic reaction. Human insulin appears to be least allergenic but occasionally may cause reactions. In some patients, insulin desensitization may be indicated.

ASPIRIN AND NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Aspirin and other NSAIDs can produce eight general types of reactions, four of which are related to cyclooxygenase inhibition.62,63 These reactions can involve asthma and rhinitis, urticaria/angioedema, anaphylaxis and anaphylactoid reactions, aseptic meningitis, or pneumonitis. The two most prevalent aspirin sensitivity reactions are respiratory (asthma, rhinorrhea) and urticaria/angioedema. Approximately 9% to 20% of asthmatics are sensitive to aspirin and other NSAIDs.62,64

The rhinosinusitis/asthma syndrome typically develops in middle-aged patients who are nonatopic and have no history of aspirin intolerance. Women are 2.5 times more likely to develop aspirin-induced asthma than men.60 It usually progresses from rhinitis to sinusitis with nasal polyps and steroid-dependent asthma. It is uncommon in children and young adults. However, children with asthma may be aspirin sensitive. Aspirin-sensitive asthma appears to be an inherited disorder characterized by overexpression of LTC4 synthase in airways.64 In aspirin-sensitive asthmatics, administration of aspirin and NSAIDs may provoke severe and sometimes fatal asthmatic attacks. The mechanism of aspirin sensitivity is not completely understood.

One suspected mechanism of aspirin and NSAID sensitivity is cyclooxygenase-1 blockade, which may facilitate depletion of prostaglandin E2 (PGE2) and production of alternative arachidonic acid metabolites (e.g., LTs).66 PGE2 prevents mast cell degranulation, whereas LTs cause bronchoconstriction and increased mucus production. Increased LT production may also explain the development of angioedema and urticaria. This proposed mechanism is supported by the observed correlation between the degree of cyclooxygenase-1 blockade and the risk of a sensitivity reaction; thus, agents such as acetaminophen, which minimally block cyclooxygenase 1, rarely cause reactions. Additional support is found in the clinical observation that LT-modifying drugs can reduce the severity of aspirin-induced asthma and urticaria.62 It is also possible that aspirin and NSAIDs stimulate mast cells directly to release inflammatory mediators. Subjects with aspirin-induced asthma also have a marked increase in airway responsiveness to LTs.67 Aspirin and the cyclooxygenase-2–selective inhibitors celecoxib and rofecoxib do not appear to be cross-reactive.68-70

In patients with aspirin sensitivity (asthma or urticaria), an oral challenge or provocation test can be performed to diagnose the
condition. A number of different protocols to detect aspirin or NSAID sensitivity have been recommended, but the risk for anaphylaxis cannot be reliably predicted.⁶²,⁶³ The challenge should be performed with great caution in a hospital setting with resuscitation equipment at hand. For patients with aspirin-induced asthma, desensitization is recommended. Aspirin desensitization has been shown to improve asthma symptom scores and lead to reductions in maintenance steroid doses. If desensitization is not performed, patients with aspirin sensitivity must avoid aspirin and the nonselective NSAIDs as the major preventive measure.

Aspirin and individual NSAIDs (e.g., ibuprofen, sulindac) can also cause IgE-mediated hypersensitivity. These reactions occur on re-exposure to the drug and may present as urticaria, bronchospasm or anaphylaxis with or without hypotension. A careful and complete allergy history may suggest true hypersensitivity to aspirin or an isolated NSAID. Such patients should be advised to avoid the specific NSAID and any structurally similar NSAIDs (e.g., all propionic acid derivatives, all indole acetic acid derivatives) because of the risk of cross-reactivity.

NSAIDs have been associated with pulmonary infiltrates and eosinophilia syndrome. Pulmonary infiltrates and eosinophilia syndrome is associated with fever, cough, dyspnea, infiltrates on chest roentgenogram, and a peripheral eosinophilia that develop 2 to 6 weeks after initiating treatment. Pulmonary infiltrates and eosinophilia syndrome occurs more frequently for naproxen compared with other NSAIDs and is noted to resolve rapidly after discontinuation of the offending agent.⁷¹

**SULFONAMIDES**

Sulfonamide drugs containing the sulfa (SO₂NH₂) moiety include antibiotics, thiazide and loop diuretics, oral hypoglycemics, and carbonic anhydrase inhibitors. Allergic reactions have been reported in 4.8% of 20,226 patients who received a sulfonamide antibiotic and in 2% of patients who received a nonantibiotic sulfonamide.⁷² Although immediate IgE-mediated reactions such as anaphylaxis can occur, sulfonamides typically cause delayed cutaneous reactions, often beginning with fever and then followed by a rash (e.g., maculopapular or morbilliform eruptions). Infrequently, a seemingly benign maculopapular rash may progress to a mucocutaneous syndrome (e.g., SJS/toxic epidermal necrolysis).¹ Other reactions to sulfonamides may include hepatic, renal, or hematologic complications, which may be fatal. Immune-mediated sulfonamide reactions depend on the production of reactive metabolites in the liver.⁷³ Trimethoprim–sulfamethoxazole, considered the most highly reactive sulfonamide, contains an arylamine in the N4 position of its chemical structure allowing for the drug’s metabolism to two highly reactive metabolites, a hydroxylamine and a nitroso-sulfonamide.⁷³,⁷⁴ Structural differences between the sulfonamides antibiotics and non-antibiotics may influence the metabolic conversion and resultant reactivity of these compounds. Slow acetylator phenotype may also increase the risk for these reactions.⁸

Cross-reactivity between sulfonamide antibiotics and non-antibiotics appears to be minimal, with cross-reactivity characterized as “highly unlikely.”⁹ In one study, about 10% of patients with history of allergy to an antibiotic sulfonamide subsequently reacted to a non-antibiotic sulfonamide (e.g., acetazolamide, loop diuretic, sulfonylurea, thiazide).⁷² This low rate of cross-reactivity has been attributed in part to differences in the chemical structures of the antibiotic and non-antibiotic sulfonamides. The occurrence of allergic reactions after receipt of non-antibiotic sulfonamides has also been attributed to a predisposition to allergic reactions in the affected individuals rather than cross-reactivity with sulfonamide antibiotics.⁷² In fact, in one study, cross-reactivity between sulfonamide antibiotics and penicillin was higher than that between the antibiotic and nonantibiotic sulfonamides.⁷³

Trimethoprim–sulfamethoxazole is used frequently for preventive or active treatment of *Pneumocystis jiroveci* pneumonia in patients with AIDS. Adverse reactions to trimethoprim–sulfamethoxazole occur much more frequently in human immunodeficiency virus (HIV)-positive patients.⁷⁶,⁷⁷ Adverse effects to trimethoprim–sulfamethoxazole occur in 50% to 80% of AIDS patients compared with 10% of other immunocompromised patients.⁷⁷ Trimethoprim–sulfamethoxazole was associated with an adverse event rate of 26.3 per 100 person-years and hypersensitivity events at 22 per 100 person-years. Although reactions may include angioedema, SJS, and thrombocytopenia, most reactions to trimethoprim–sulfamethoxazole in HIV-infected patients are delayed and present as diffuse maculopapular rash with or without fever. The mechanism by which these allergic or allergic-like reactions occur in HIV-infected patients is unclear. It is unlikely that these reactions are IgG or IgE-mediated.⁷⁶,⁷⁷ Theories support alterations in drug metabolism due to glutathione deficiency, a direct toxic or immunologic effect of the sulfonamide metabolites on body tissues, and increased expression of major histocompatibility complex proteins with increased recognition of the drug antigen by CD4 and CD8 cells.⁷³,⁷⁸ The adverse event rate has been related to higher CD4+ T cell count >20 cells/mm³ (>20 × 10⁶/L), CD4/CD8 ratio <0.10 and treatment for less than 14 days.⁷⁷

**PHARMACEUTICAL EXCIPIENTS AND ADDITIVES**

Pharmaceutical products contain a number of “inert” additives (e.g., dyes, fillers, buffers, and stabilizers) in addition to the therapeutic ingredients. These additives are not always inert and may cause adverse effects, including allergic reactions.

The azo dye tartrazine (FD&C Yellow No. 5) is associated with anaphylactoid reactions, acute bronchospasm, urticaria, rhinitis, and contact dermatitis.⁷⁹,⁸⁰ Although the immunologic mechanisms are unclear, approximately 10% of aspirin-sensitive asthmatics are also intolerant to tartrazine,¹¹ suggesting a role for tartrazine as a cyclooxygenase inhibitor. As little as 0.85 mcg or as much as 25 mg tartrazine has provoked positive responses.¹¹

Sulfites (including sulfur dioxide, sodium sulfite, sodium and potassium bisulfite, and sodium and potassium metabisulfite) are used commonly as antioxidants in pharmaceutical products and some foods. Many cases of adverse reactions associated with ingestion of sulfites (usually in foods) have been reported to the U.S. Food and Drug Administration (FDA),¹² including wheezing, dyspnea, chest tightness, urticaria, angioedema, flushing, weakness, nausea, anaphylaxis, and death. IgE-mediated and nonimmunologic sulfite hypersensitivity has been demonstrated in children with a history of chronic asthma. Adverse reactions to sulfite-preserved injectables, such as gentamicin, metoclopramide, lidocaine, and doxycycline, have been reported. In contrast to reactions caused by foods, these reactions do not occur more frequently in steroid-dependent asthmatics and do not always coincide with a positive oral sulfite challenge.¹³ Blunted bronchodilation may be observed in asthmatics following inhalation of sulfite-containing nebulizer solutions. Although many nebulizer solutions contain sulfites, metered-dose inhalers do not. Many aqueous epinephrine products also contain sulfites. The FDA labeling states that in emergency situations when sulfite-free preparations are not available, sulfite-containing epinephrine should not be withheld from a sulfite-intolerant individual because small subcutaneous doses of sulfites usually are well tolerated. However, an increased risk of anaphylaxis exists after subcutaneous injection in rare patients with a positive oral challenge to 5 to 10 mg sulfite.
Parabens (including methyl-, ethyl-, propyl-, and butylparaben) are used widely in pharmaceutical products as a biocidal agent. Most allergic reactions to parabens are observed after topical exposure. Delayed hypersensitivity contact dermatitis occurs more often in individuals with preexisting dermatitis. Immediate hypersensitivity after parenteral administration is rare. Although these agents are chemically related to benzoic acid and p-aminobenzoic acid, the evidence for cross-sensitivity is lacking.

**CANCER CHEMOTHERAPY AGENTS**

Chemotherapy agents are implicated in hypersensitivity reactions in 5% to 15% of patients who receive them. Up to 65% of patients receiving L-asparaginase experience immediate hypersensitivity reactions such as urticaria and anaphylaxis.

The combination regimen of paclitaxel (or docetaxel) and carboplatin frequently is responsible for producing hypersensitivity reactions. Each agent precipitates a distinct reaction, allowing for differentiation between causative factors. Hypersensitivity reactions have been observed with paclitaxel and docetaxel as frequently as 34% of patients. The reaction, typically occurring shortly after initiation of the first dose, is due to Cremophor EL, the polyoxyethyalted castor oil vehicle for paclitaxel. Severe reactions are characterized by dyspnea, bronchospasm, urticaria, and hypotension. Minor reactions include flushing and rashes. In patients receiving a 3-hour infusion, the incidence of severe reactions is reduced to 1.3%, and the incidence of minor reactions is 42%. To reduce the risk of hypersensitivity reaction, patients are routinely premedicated with corticosteroids and H$_2$ and H$_{1}$-receptor antagonists. A protein-bound formulation of paclitaxel (Abraxane) is available that avoids most of the hypersensitivity reactions.

Carboplatin hypersensitivity develops after six or more courses of carboplatin or its parent compound cisplatin. Reactions typically develop shortly after completing the infusion or up to 3 days after therapy. Symptoms of severe reaction include tachycardia, dyspnea, facial swelling, rigors, and hypotension. Mild reactions include itching, erythema, and facial flushing. Both skin testing with carboplatin and desensitization have been shown to be effective.

Oxaliplatin hypersensitivity has been reported in as many as 12% of patients. Symptoms range from facial flushing to dyspnea. Management strategies include decreasing the rate of infusion and administration of corticosteroids and H$_2$ and H$_{1}$-receptor antagonists. Desensitization has been successful in patients desiring to continue treatment after experiencing a hypersensitivity reaction.

**ANTICONVULSANTS**

Many anticonvulsant drugs produce a variety of hypersensitivity reactions and pseudoallergic reactions. Drugs such as phenytoin, phenobarbital, carbamazepine, and lamotrigine can cause an “anti-convulsant hypersensitivity syndrome” characterized by fever, rash, lymphadenopathy, and internal organ involvement. Eosinophilia is frequently present and many reactions meet the definition of DRESS. Onset usually occurs several weeks into therapy. In some cases, morbilliform rash develops into exfoliative dermatitis. The risk of cross-reactivity between the aromatic anticonvulsants (e.g., carbamazepine, phenobarbital, and phenytoin) ranges from 40% to 80%. Oxcarbazepine, the 10-keto derivative of carbamazepine, has exhibited both in vitro and in vivo cross-reactivity with carbamazepine. A genetic marker for severe reactions to carbamazepine, phenytoin and fosphenytoin is the presence of the HLA-B*1502 allele. This allele is found in 10% to 15% of patients from China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan. Concomitant use of valproate with lamotrigine significantly increases the risk of hypersensitivity as a result of reduced lamotrigine metabolism, leading to a prolonged elimination half-life.

**BIOLOGICS**

Biologic agents (e.g., monoclonal antibodies, fusion proteins, recombinant proteins) are derived from living sources such as yeast, bacteria, animal cells, or mammalian cells. Unlike nonbiologic agents, these large proteins can serve as complete antigens. Examples include recombinant insulin, erythropoetin, interferon-$eta$, human growth hormone, infliximab, rituximab, and omalizumab. Immunologic reactions to these agents range from minor infusion or injection-site reactions to anaphylaxis. Depending on the agent, reactions can occur on first or subsequent exposure and the timing may be within 4 hours of drug administration or up to 14 days after an infusion.

Factors influencing the antigenicity of biologic agents are patient-specific (e.g., atopy, congenital protein deficiency), production-related (e.g., presence of contaminants or stabilizing agents, degree of protein glycosylation, presence of nonhuman protein sequences, storage temperature), and administration-related (e.g., route of administration, frequency of use, concurrent immunosuppressant use). Of the monoclonal antibodies, reactions are most frequently observed with the murine-derived agents (0% human) and chimeric agents (75% human) as opposed to the humanized (>90% human) and human (100% human) agents. Some immune reactions to biologic agents result from the development of neutralizing antibodies that can prevent the protein from exerting its intended effect. Neutralizing antibodies have been shown to mediate reactions to interferon-$eta$, infliximab, natalizumab, recombinant factor VIII, and recombinant factor IX.

Anti-infliximab antibodies, which occur in up to 60% of treated patients, are associated with higher frequency of infusion reactions and decreased therapeutic effect. Concomitant administration of immunosuppressant agents such as prednisone or low dose methotrexate has been shown to decrease the incidence of antibody formation to infliximab.

Delayed onset anaphylaxis, ranging from minutes to days post-injection, has been reported with omalizumab, a humanized monoclonal antibody targeted against IgE. Omalizumab-treated patients require extended observation post-injection and are advised to carry an epinephrine auto-injector during and for 24 hours after drug administration. Risk factors for this adverse event have not been identified. Inclusion of polysorbate 80 as a stabilizing agent in the formulation, and an alteration in the protein sequence via glycosylation, may influence the immunogenicity of omalizumab.

Management of allergic or allergic-like reactions to biologic agents varies based on the culprit agent and the severity and nature of the reaction. Immediate management with epinephrine and permanent discontinuation of the drug may be warranted (e.g., omalizumab-induced anaphylaxis). Depending on the biologic agent, reactions may be managed by decreasing the infusion rate or lessened by pretreating with antihistamines and/or corticosteroids or administering concomitant steroid therapy.

**TREATMENT**

### Allergic Reactions

The basic principles for management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.
**TABLE 97–4 Treatment of Anaphylaxis**

1. Place patient in recumbent position and elevate lower extremities.
2. Monitor vital signs frequently (every 2–5 minutes) and stay with the patient.
3. Administer epinephrine 1:1,000 into nonocluded site: (adults: 0.01 mL/kg up to a maximum of 0.2–0.5 mL every 5 minutes as needed; children: 0.01 mL/kg up to a maximum dose of 0.2–0.5 mL) subcutaneously or intramuscularly. If necessary, repeat every 5 minutes, up to 2 doses, then every 4 hours as needed.
4. Administer oxygen, usually 8–10 L/min; however, lower concentrations may be appropriate for patients with chronic obstructive pulmonary disease. Maintain airway with oropharyngeal airway device.
5. Administer the antihistamine diphenhydramine (Benadryl, adults 25–50 mg; children 1–2 mg/kg) usually given parenterally. Apply tourniquet proximal to site of antigen injection; remove every 10–15 minutes. Consider ranitidine 1 mg/kg diluted in D5W to a total volume of 20 mL given IV over 5 minutes.
6. If anaphylaxis is caused by an injection, administer aqueous epinephrine 1:1,000 into site of antigen injection; 0.15–0.3 mL into the injection site.
7. Treat hypotension with IV fluids or colloid replacement, and consider use of a vasopressor such as dopamine.
8. Treat bronchospasm resistant to epinephrine with nebulized albuterol 2.5–5 mg in 3 mL saline every 20 minutes for 3 doses; in children, 0.15 mg/kg via nebulizer every 20 minutes for 3 doses.
9. Give hydrocortisone, 5 mg/kg, or approximately 250 mg IV (prednisone 9.20 mg orally can be given in mild cases) to reduce the risk of recurring or protracted anaphylaxis. These doses can be repeated every six hours as required.
10. In refractory cases not responding to epinephrine because a β-adrenergic blocker is complicating management, glucagon 1 mg IV as a bolus may be useful. A continuous infusion of glucagon, 1–5 mg/h, may be given if required.

**ANAPHYLAXIS**

Anaphylaxis requires prompt treatment to minimize the risk of serious morbidity or death. On presentation, attention should be given first to stopping the likely offending agent, if possible, and restoring respiratory and cardiovascular function. A protocol for treatment of anaphylaxis is presented in Table 97–4. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilation. Epinephrine should be administered intramuscularly in the lateral aspect of the thigh. If blood pressure is not restored by epinephrine, crystalloid intravenous fluids should be administered to restore intravascular volume. Typically, 1 L of 0.9% sodium chloride or lactated Ringer solution is administered over 10 to 15 minutes. This can be repeated if the patient is still believed to be volume depleted. A maintenance intravenous fluid then is initiated. Intravenous fluids should be given early in the course of treatment in an attempt to prevent shock. An immediate priority is to establish and maintain an airway by the use of endotracheal intubation if necessary. When a patient with anaphylaxis is hypotensive, vasoressors may be needed in addition to crystalloids. Norepinephrine is the vasoconstrictor agent of choice for treatment of anaphylactic shock, although dopamine also may be useful. Patients in shock should remain supine with raised legs.

Other agents may be required for treatment of anaphylactic reactions. Corticosteroids (hydrocortisone sodium succinate intravenously) can reduce the risk of late-phase reactions. In patients treated chronically with β-blockers, glucagon should be considered because its inotropic and chronotropic effects do not rely on β-receptor responsiveness. Histamine (H1) receptor blockers (e.g., diphenhydramine) can be administered to reduce some of the symptoms associated with anaphylaxis, but these agents are not effective as primary therapy. The combination of diphenhydramine and an H2 receptor blocker (e.g., ranitidine) has been shown to be superior to diphenhydramine alone in the treatment of anaphylaxis.
for side chain mediated reactions. The value of skin testing to predict the risk of allergic reactions to other antibiotics (e.g., sulphonamides, tetracyclines, fluoroquinolones) is largely unknown.

Skin testing is used to identify patients at risk for hypersensitivity reactions to carboplatin. The negative predictive value of intradermal skin testing with carboplatin has been shown to be 98% to 99% in patients who have received a number of treatment courses.

### DESENSITIZATION

For some patients with history of immediate penicillin or β-lactam allergy, no reasonable alternatives exist, and penicillin or a related β-lactam may be necessary for treatment of severe, life-threatening infection. In this situation, desensitization to the specific β-lactam required for treatment of the infection should be considered. Desensitization can reduce the risk of an IgE-mediated reaction such as anaphylaxis by rendering the mast cells less responsive to degranulation. Desensitization does not influence the likelihood of other types of reactions such as exfoliative dermatitis or SJS.

Desensitization should be performed by a physician experienced in the risks and management of severe allergic reactions in a hospital setting with resuscitation equipment available. The potential risks and benefits should be discussed with the patient. Desensitization should be performed with the specific β-lactam antibiotic that will be administered for treatment of the patient’s infection. Prior to initiating the protocol, the patient should be stabilized and fluid, pulmonary, and cardiovascular function optimized. Premedication (antihistamines or corticosteroids) should not be used because these agents may mask the early signs of acute reactions and do not reliably reduce the severity of acute reactions. Approximately one third of patients who have undergone desensitization experience mild, transient allergic reactions either during the desensitization procedure or during penicillin therapy.

Patients who can take oral medication should undergo desensitization with oral drug. Once the desensitization protocol is begun, it should not be interrupted except for severe reactions. Antihistamines or epinephrine can be administered to treat reactions. In addition, if the patient completes the desensitization regimen and then undergoes full dose treatment, a lapse between doses of as few as 24 hours can allow for reemergence of sensitivity. Protocols for oral and intravenous penicillin desensitization are listed in Tables 97–6 and 97–7.

</table>

1. Place a drop of each test material on the volar surface of the forearm.
2. Prick the skin with a sharp needle inserted through the drop at a 45° angle, gently tenting the skin in an upward motion.
3. Interpret skin responses after 15 minutes.
4. A wheal at least 2 × 2 mm with erythema is considered positive.
5. If the prick test is nonreactive, proceed to the intradermal test.
6. If the histamine control is nonreactive, the test is considered uninterpretable.

*Administer doses at intervals of not less than 20 min.
*Observe and record skin wheal-and-flare response.
Protocols for desensitization with other β-lactam antibiotics are also available.11,12

Skin tests to penicillin often become negative during and shortly after desensitization. The mechanism by which desensitization is protective is unclear. It does not appear that penicillin-specific IgE is neutralized or that IgG as “blocking antibody” is produced. One possible explanation is that basophils and mast cells attain some degree of tolerance on exposure to the antigen.

Although most reactions to trimethoprim-sulfamethoxazole in HIV-infected patients are not considered to be IgE mediated, the term trimethoprim-sulfamethoxazole desensitization is commonly recognized. The underlying mechanism by which desensitization to trimethoprim–sulfamethoxazole is achieved in these patients remains unknown. A number of protocols for trimethoprim–sulfamethoxazole desensitization are available, and many are also referred to as graded challenge protocols. Since these regimens have not been compared in controlled clinical trials, there is no preferred regimen. Desensitization of trimethoprim–sulfamethoxazole can be achieved within 2 days in most AIDS patients.1,113 This can be accomplished by using the following schedule of oral doses (milligrams of sulfamethoxazole–trimethoprim): day 1: 9 am, 4 and 0.8 mg; 11 am, 8 and 1.6 mg; 1 pm, 20 and 4 mg; 5 pm, 40 and 8 mg; day 2: 9 am, 80 and 16 mg; 3 pm, 160 and 32 mg; 9 pm, 200 and 40 mg; day 3: 9 am, 400 and 80 mg, and 400 and 80 mg daily thereafter. With this desensitization regimen, the failure rate was associated with higher relative and absolute CD4 cell counts. Other investigators have described a 6-hour oral graded challenge in HIV-infected patients,114 and a more gradual 9-day oral regimen.115 Desensitization should not be attempted in any patient with history of an exfoliative reaction to trimethoprim-sulfamethoxazole.

Both rapid (over less than 4 hours) and traditional desensitization protocols are available for aspirin and clopidogrel.116-117 Aspirin desensitization is more effective in patients with history of aspirin-induced asthma as compared to the angioedema/urticarial presentation.118 A rapid 12-step protocol has been shown to be safe and effective for desensitizing patients to a variety of chemotherapeutic agents including carboplatin, cisplatin, oxaliplatin, paclitaxel, and rituximab.93

### GRADED CHALLENGE

Also known as test dosing, a graded drug challenge involves the gradual introduction of a drug when there is a risk of reactivity. A graded drug challenge does not modify the immune response or allow for more rapid desensitization.111 Instead, graded challenge is used when the risk of a severe reaction to a drug on re-exposure is low, no alternative drug is equally effective, and a reliable skin testing method is not available. A classic example is the gradual re-introduction of trimethoprim–sulfamethoxazole in a patient who had a mild maculopapular rash to the drug in the past. Graded challenge may also be used to test for cross-reactivity when the risk of a severe reaction is low (e.g., a patient with history of allergy to one cephalosporin who now requires a cephalosporin having a dissimilar R1 side chain).111 Graded challenge protocols have been described for the slow introduction of furosemide in a patient with heart failure and history of sulfonamide allergy.119 Challenge dosing is not recommended when there is history of a severe drug allergy (e.g., anaphylaxis, SJS, TEN). Premedications should not be used because they may mask signs of an early breakthrough allergic reaction. The starting dose is typically 1/100th to 1/1000th of the therapeutic dose and the oral route of drug administration is preferred to limit the risk of a severe reaction.110 If no reaction occurs to the initial dose, the dose may be increased in 2- to 5-fold increments and administered every 30 to 60 minutes until the full therapeutic dose is achieved.89,111 There is no standard protocol for graded challenge dosing; a therapeutic dose may be achieved over a matter of hours or days. Due to the risk of break-through allergic reactions, graded challenges should be performed in monitored settings.

### ABBREVIATIONS

- APC: antigen-presenting cell
- DRESS: drug rash with eosinophilia and systemic symptoms
- HLA: human leukocytic antigen
- IgE: immunoglobulin E
- LT: leukotriene
- NSAID: nonsteroidal antiinflammatory drug
- PAF: platelet-activating factor
- PG: prostaglandin
- PPD: purified protein derivative
- SJS: Stevens Johnson syndrome
- SLE: systemic lupus erythematosus
- TEN: toxic epidermal necrolysis

KEY CONCEPTS

1. A combination of two to four immunosuppressive drugs is used to target different levels of the immune cascade to prevent allograft rejection and allow lower doses of the individual agents to minimize their toxicity.

2. Calcineurin inhibitors (CIs), such as cyclosporine and tacrolimus, which inhibit interleukin (IL)-2 and thus block T-cell activation are the backbone of immunosuppressive regimens. However, they are associated with significant adverse effects, namely, nephrotoxicity and neurotoxicity.

3. Calcineurin inhibitor–induced nephrotoxicity is one of the most common side effects observed in transplant recipients and is the leading cause of renal dysfunction in nonrenal transplant patients. Therapeutic drug monitoring is used in an attempt to optimize the use of calcineurin inhibitors.

4. Corticosteroids are a key component of immunosuppressive regimens because they block the initial steps in allograft rejection. However, the adverse effects associated with their long-term use have prompted the investigation of corticosteroid–free immunosuppressive protocols. Corticosteroids remain the cornerstone of the treatment of allograft rejection.

5. Antiproliferative agents such as azathioprine and mycophenolate inhibit T-cell proliferation by altering purine synthesis to prevent acute rejection. Bone marrow suppression is the most significant adverse effect associated with these agents.

6. Sirolimus and everolimus exert their activity by inhibiting the mTOR (mammalian target of rapamycin) receptor, which alters T-cell response to IL-2. The adverse effects associated with sirolimus include thrombocytopenia, anemia, and hyperlipidemia.

7. Antibody preparations that target specific receptors on T cells are classified as depleting or nondepleting. Most lymphocyte-depleting antibodies are associated with significant infusion-related reactions.

8. Long-term allograft and patient survival is limited by chronic rejection, cardiovascular disease, and long-term immunosuppressive complications such as malignancy.

Solid-organ transplantation provides a lifesaving treatment for patients with end-stage cardiac, kidney, liver, lung, and intestinal disease. About 250 U.S. hospitals offer transplant services, and pharmacists are often an integral part of the transplant team. The Centers for Medicare and Medicaid Services regulations require that transplant programs have a multidisciplinary team including individuals with experience in pharmacology. While the regulations do not specifically state that each center must have a pharmacist, a pharmacist would certainly provide the desired expertise in transplant pharmacotherapy that the regulations mandate.

With the success of transplantation, an increasing number of transplant recipients are in our communities. By the end of 2005 there were more than 160,000 people living with a solid-organ transplant in the United States. In 2008, 27,963 solid-organ transplants were performed. Kidney transplants remain the most common; 10,551 were from cadaveric donors and 5,967 from living donors. The next most frequently transplanted organ was the liver, with 6,070 from cadaveric donors and 249 from living donors. Heart and pancreas (or combined kidney–pancreas) transplants account for over 2,100 and almost 1,300 transplants, respectively; over 1,900 lung transplants were performed as well. While the demand for transplantation continues to grow, the number of cadaveric donors has remained relatively stable during the past decade. In 2008, more than 100,000 persons in the United States were waiting for a transplant (almost 70,000 people were awaiting a kidney, 16,000 a liver, and almost 3,000 were on the list for a heart transplant). Median waiting time for a cadaveric kidney is more than 3.5 years. For liver transplantation the median time to transplant is about 1 year, whereas for heart transplantation it is approximately 6 months. For heart, liver, and lung transplantation clinical status is an important factor affecting waiting times, with the sickest patients receiving priority for available organs.

To increase the number of organs available for transplantation, several strategies have been employed in the past several years. The use of living donors for renal transplantation represents over one third of all kidney transplants, more than any other organ. Living-donor transplantation is also becoming increasingly important for those with end-stage liver and lung disease. Efforts to expand the cadaveric donor pool have included relaxation of age restrictions, development of better preservation solutions, use of “extended-criteria” and non–heart-beating donors, and the transplantation of one liver to more than one recipient, as well as the implantation of only a segment of a liver. Although very controversial, others advocate the creation of a regulated system for compensating individuals in a monetary fashion for the “donation” of a kidney.

Despite all these efforts, patients continue to die awaiting transplantation. In 2004, more than 7,000 people who were on transplantation waiting lists died. In all areas, efforts have been made to improve organ allocation by moving toward allocation based primarily on “medical necessity” versus time on the waiting list.
Although dialysis can be used for an extended period of time to partially replace the function of the kidneys, such options are not readily available for most liver and heart transplantation candidates. Left ventricular assist devices are now used commonly as a bridge to transplantation for many heart transplantation candidates, however, hepatocyte transplantation and artificial liver support remain investigational alternatives or bridges to liver transplantation.

Patient and graft survival rates following transplantation have improved significantly over the past 30 years as a result of advances in pharmacotherapy, surgical techniques, organ preservation, and the postoperative management of patients (Table 98–1). In this chapter the epidemiology of end-stage kidney, liver, and heart disease is briefly reviewed, the pathophysiology of organ rejection is reviewed, the pharmacotherapeutic options for individualized immunosuppressive regimens are critiqued, and the unique complications of these regimens along with the therapeutic challenges they present are discussed.

### EPIDEMIOLOGY AND ETIOLOGY

#### KIDNEY

Renal transplantation is the preferred long-term therapeutic option for most patients with end-stage renal disease because it provides patients with the greatest potential improvement in quality of life. Dialysis catheter-related infections, peritoneal dialysis-associated peritonitis, and scheduled dialysis treatments are avoided, and dietary restrictions are fewer. Patients who receive a renal transplant before the initiation of dialysis have markedly improved quality of life and prolonged life expectancy. The use of living-donor transplantation has made this increasingly possible. Although the analysis of quality of life is complex, patients generally report improved quality of life following transplantation as compared with patients on maintenance dialysis.

Diabetes mellitus, hypertension, and glomerulonephritis are the most common causes of end-stage renal disease leading to kidney transplantation and account for more than 70% of patients (see Chap. 52 and 53). Patients with medical conditions such as unstable cardiac disease or recently diagnosed malignancy, for whom the risk of surgery or chronic immunosuppression would be greater than the risks associated with chronic dialysis, are generally excluded from consideration for transplantation.

#### LIVER

Noncholestatic cirrhosis (hepatitis C, alcoholic cirrhosis, hepatitis B, nonalcoholic steatohepatitis, and autoimmune hepatitis) is the primary cause of end-stage liver disease and more than 70% of liver transplant recipients have been diagnosed with one of these conditions. Livers are allocated based on a United Network for Organ Sharing–adapted, Model for End-stage Liver Disease (MELD) score. This score, based on serum creatinine concentration, total serum bilirubin concentration, international normalized ratio, and etiology of cirrhosis, has been demonstrated to be a useful tool to predict impending mortality.

There are few absolute contraindications to liver transplantation. Patients should be free from active alcohol or substance abuse. Although hepatitis B and C can recur in the transplanted liver, these are not absolute contraindications to liver transplantation.

#### HEART

Cardiac transplant candidates are typically patients with end-stage heart failure who have New York Heart Association class III or IV symptoms despite maximal medical management and have an expected 1-year mortality risk of 25% or greater without a transplant. Idiopathic cardiomyopathy and ischemic heart disease account for heart failure in more than 90% of heart transplantation recipients. Other etiologies include valvular disease, retransplantation for graft atherosclerosis or dysfunction, and congenital heart disease. Chapters 20 and 21 discuss the role of heart transplantation as a therapeutic option for patients with heart failure.

Absolute contraindications to orthotopic cardiac transplantation include the presence of an active infection (except in the case of an infected ventricular assist device, which is an indication for urgent transplantation) or the presence of other diseases (e.g., malignancy) that may limit survival and/or rehabilitation and severe, irreversible pulmonary hypertension.

#### PHYSIOLOGIC CONSEQUENCES OF TRANSPLANTATION

Transplantation is truly lifesaving for heart, liver, and lung transplantation recipients, whereas renal transplantation is associated with improved quality of life and survival when compared with dialysis. Most heart transplantation patients return to New York Heart Association functional class I following transplantation. Although not all return to work, 89.9% of patients consider themselves to have no activity limitations at 1-year follow-up. The specific physiologic consequences of kidney, liver, and heart transplantation are discussed next.

#### KIDNEY TRANSPLANTATION

The glomerular filtration rate of a successfully transplanted kidney may be near normal almost immediately after transplantation. In some patients, however, the concentration of standard biochemical indicators of renal function, such as serum creatinine and blood urea nitrogen, may remain elevated for several days. Standard formulas used to predict drug dosing rely on a stable serum creatinine and may be inaccurate immediately following transplantation (see Chap. 50).
Although the allograft is able to remove uremic toxins from the body, it may take several weeks for other physiologic complications of chronic renal failure, such as anemia, calcium and phosphate imbalance, and altered lipid profiles, to resolve. The renal production of erythropoietin and 1-hydroxylation of vitamin D may return toward normal early in the postoperative period. Because the onset of physiologic effects may be delayed, continuation of pretransplantation calcitriol, calcium supplementation, and/or phosphate binders may be warranted. The duration of therapy will depend on how rapidly kidney function improves. Patients should be monitored for hypophosphatemia and hypercalcemia.

Primary nonfunction of a renal allograft or delayed graft function (DGF) is characterized by the need for dialysis in the first postop week or the failure of the serum creatinine to fall by 30% of the pretransplantation value. The incidence of DGF in cadaveric renal transplantation ranges from 8% to 50% and results in a slower return of the kidney’s excretory, metabolic, and synthetic functions. DGF is associated with prolonged hospital stays, higher costs, difficult management of immunosuppressive therapy, slower patient rehabilitation, and poor graft survival. Other early causes of renal dysfunction such as urethral obstruction or arterial or venous stenosis or thrombosis should be distinguished from DGF.

The primary cause of DGF is acute tubular necrosis (ATN). The incidence of ATN increases when kidneys are harvested from donors who recently experienced a cardiac arrest, from donors who were hypotensive or on vasopressors, or from older donors (age >55 years) and with prolonged periods of ischemia. While cyclosporine and tacrolimus have been implicated in the prolongation of ATN, a clear cause-and-effect relationship has not been established. Nonetheless, most clinicians will decrease calcineurin inhibitor doses in patients with ATN. DGF predisposes patients to acute rejection, possibly as a consequence of decreased calcineurin inhibitor levels and a resultant reduction in the level of immunosuppression.

**LIVER TRANSPLANTATION**

The physiologic consequences of liver transplantation are complex, involving changes in both metabolic and synthetic function. Postoperatively, the liver transplant recipient will likely have many fluid, electrolyte, and nutritional abnormalities. Biliary tract dysfunction may alter the absorption of fats and fat-soluble drugs. Poor absorption of the lipid-soluble drug cyclosporine improves after successful liver transplantation and reestablishment of bile flow. Vitamin E deficiency and its neurologic complications in liver failure patients are reversed after successful liver transplantation. In stable adult liver transplant patients, the concentrations of retinol and tocopherol are similar to those seen in normal healthy subjects, indicating recovery of transplanted liver production and excretion of bile salts needed for fat-soluble vitamin absorption.

Table 98–2 summarizes the effects of liver transplantation on metabolism and renal elimination that are seen in the immediate postoperative period. Most of these changes resolve as liver function normalizes.

The newly transplanted liver fails to function in 10% to 15% of recipients as the result of several different mechanisms. Early graft failure can result from preexisting disease in the donor, and even coagulation defects have been acquired through donor organs. The technical complexity of the operation can produce flaws in revascularization that also lead to graft nonfunction. Surgical complications include portal vein or hepatic artery thrombosis and bile duct leaks. Ischemic injury can also result in early graft dysfunction. While hyperacute rejection in liver transplantation rarely occurs, graft failure in the first 2 postoperative weeks may indicate antibody-mediated graft destruction.

**HEART TRANSPLANTATION**

The orthotopically transplanted heart is denervated and no longer responds to physiologic stimuli and pharmacologic agents in a normal manner (Table 98–3). Patients, for example, do not experience angina. In situations requiring an increased heart rate such as exercise or hypotension, the denervated heart is unable to acutely increase heart rate but instead relies on increasing the stroke volume. Later in the course of exercise or hypotension, heart rate increases in response to circulating catecholamines. While the maximum exercise capacity of heart transplant recipients is below normal, most patients are able to resume normal lifestyles and reasonably vigorous activity levels. Partial reinnervation may occur over time, thereby facilitating more normal physiologic and pharmacologic responses and better exercise capacity.

A number of autoregulatory, anatomic, and physiologic responses present in the normal heart are interrupted or blunted for the first 6 weeks after transplantation. The donor sinus node function may be impaired by preservation injury, direct surgical trauma at excision, the presence of long-acting antiarrhythmics (e.g., amiodarone) taken prior to transplant by the recipient, and a lack of “conditioning” responsiveness to catecholamines. Consequently, the transplanted heart generally requires chronotropic support with either milrinone or pacing in the perioperative period to maintain a heart rate of 90 to 110 beats per minute and satisfactory hemodynamics (i.e., blood pressure, urine output, and tissue perfusion). Approximately 10% to 20% of transplant patients will have persistent chronotropic incompetence requiring either short courses of medications, such as terbutaline or theophylline, or permanent cardiac pacing.

Right ventricular function is frequently impaired, presumably as a result of preservation injury and elevated pulmonary vascular...

resistance. A “restrictive” hemodynamic pattern may be present initially but usually improves in 6 weeks following transplantation. Donor–recipient size mismatch may contribute to early post-transplantation hemodynamic abnormalities characterized by higher right and left ventricular end-diastolic pressures. Supraventricular arrhythmias are usually transient and may result from overvigorous use of catecholamines or milrinone. If this type of arrhythmia occurs after the perioperative period, the astute clinician should consider the possibility of acute rejection.

Myocardial depression frequently occurs and generally requires inotropic support with agents such as dobutamine, milrinone, and epinephrine. On occasion, intra- or postoperative administration of vasodilators, including nitric oxide, and inotropic agents may be necessary to treat right-sided failure in the transplant patient; milrinone and isoproterenol are preferred in this setting.

Persistent abnormalities of diastolic function are often noted in the transplanted heart such that intracardiac pressures increase in an exaggerated fashion in response to exercise and/or volume infusion.10 These abnormalities are due in part to denervation, but also to acute rejection or to the scarring secondary to previously treated rejection episodes, hypertension, or cardiac allograft vasculopathy.

Hypertension may occur following surgery secondary to the effect of elevated catecholamine levels and systemic vascular resistance as the residual effects of end-stage heart failure on the healthy heart. Systolic blood pressure should be maintained at 110 to 120 mm Hg to enhance cardiac function. In the acute post-transplantation period, intravenous nitroprusside or nitroglycerin may be needed, whereas oral angiotensin-converting enzyme inhibitors (ACEIs) and/or amlodipine are commonly used once the patient can ingest oral medications.

PATHOPHYSIOLOGY OF REJECTION

GENERAL CONCEPTS

Rejection of any transplanted organ is primarily mediated by activation of alloreactive T cells and antigen-presenting cells such as B lymphocytes, macrophages, and dendritic cells. Acute allograft rejection is caused primarily by the infiltration of T cells into the allograft, which triggers inflammatory and cytotoxic effects on the graft. Complex interactions between the allograft and cellular cytokines, cell-to-cell interactions, CD4+ and CD8+ T cells, and B cells ultimately lead to chronic rejection and graft loss if adequate immunosuppression is not maintained.12

The sequence of events that underlies graft rejection is recognized, via MHC class I and II antigens, of the donor’s histocompatibility differences by the recipient’s immune system, recruitment of activated lymphocytes, initiation of immune effector mechanisms, and finally graft destruction. The specifics of this immune cascade of organ rejection are discussed in Chapter 95. The complex nature of cytokine interactions makes it very difficult to design drugs with exclusive actions (Fig. 98–1).

Rejection of the transplanted tissue can take place at any time following surgery and is classified clinically as hyperacute rejection, acute cellular rejection, and/or humoral or chronic rejection.13

Efforts are made to allocate well-matched, according to human leukocyte antigens (HLA)-A, -B, and -DR, kidneys to minimize rejection and enhance survival rates. However, the benefit of having no recipient donor mismatches may be negated by excessive cold ischemia time (>36 hours) and donor age older than 60 years. HLA tissue matching is not performed routinely before transplantation for livers and hearts because organ availability is more limited and the optimal cold ischemia time is shorter. However, if the potential recipient’s blood is reactive against a panel of random donor blood samples (i.e., panel reactive antibody [PRA] >10% to 20%), a negative T-cell crossmatch is required prior to transplantation. Transplanted organs must be matched for ABO blood group compatibility with the recipient as ABO mismatching will result. Liver transplantation may be carried out in emergency situations across ABO blood groups, but survival is lower.

HYPERACUTE REJECTION

Hyperacute rejection may be evident within minutes of the transplantation procedure when preformed donor-specific antibodies are present in the recipient at the time of the transplant. Hyperacute rejection can also be induced by immunoglobulin G antibodies that bind to antigens on the vascular endothelium, such as class I MHC, ABO, and vascular endothelial cell antigens. Tissue damage can be mediated through antibody-dependent, cell-mediated cytotoxicity or through activation of the complement cascade. The ischemic damage to the microvasculature rapidly results in tissue necrosis.
Hyperacute rejection has become uncommon in kidney and heart transplants. A positive crossmatch presents a serious risk for graft failure even if hyperacute rejection does not occur. A negative lymphocytotoxicity crossmatch does not entirely rule out the possibility of hyperacute rejection because non-MHC antigens on the vascular endothelium can serve as targets of donor-specific antibodies. Early graft dysfunction is treated with supportive care and retransplantation if possible. The reason for the rarity of hyperacute rejection in liver transplantation is not fully understood, but the local release of cytokines may alter the immunologic reaction in the liver.

**ACUTE CELLULAR REJECTION**

Acute rejection is most common in the first few months following transplantation but can occur at any time during the life of the allograft. Acute cellular rejection is mediated by alloreactive T-lymphocytes that appear in the circulation and infiltrate the allograft through the vascular endothelium. After the graft is infiltrated by lymphocytes, the cytotoxic cells specifically target and kill the functioning cells in the allograft. At the same time, local release of lymphokines attracts and stimulates macrophages to produce tissue damage through a delayed hypersensitivity–like mechanism. These immunologic and inflammatory events lead to nonspecific signs and symptoms including pain and tenderness over the graft site, fever, and lethargy.

**Kidney**

Acute rejection, which may affect up to 20% of patients during the first 6 months following transplantation, is evidenced by an abrupt rise in serum creatinine concentration of ≥30% over baseline. A specific histologic diagnosis can be obtained via biopsy of the allograft and is often used to guide therapy for rejection. A biopsy specimen with a diffuse lymphocytic infiltrate is consistent with acute cellular rejection. After the diagnosis of rejection has been confirmed, the potential risks and benefits of specific antirejection therapies must be evaluated. Hypertension often worsens during an episode of rejection, and edema and weight gain are common as a result of sodium and fluid retention. Symptomatic azotemia may also develop in severe cases.

**Liver**

The liver is more likely to promote immunologic tolerance than the other vascularized organs. Approximately 18% of liver transplantation recipients will experience a rejection episode in the first post-transplant year. The clinical signs of acute cellular rejection include leukocytosis and a change in the color or quantity of bile for those who still have an external drainage tube in place. A serum bilirubin 50% over baseline or increases in hepatic transaminases to values more than three times the upper limit of normal, are sensitive markers of rejection. Although a liver biopsy provides definitive evidence of the diagnosis of rejection, a prompt response to antirejection medication has also proven useful as a means to differentiate rejection from other causes of hepatic dysfunction.

**Heart**

More than 60% of heart transplantation recipients will experience at least one episode of acute rejection during the first year, with 90% of all rejections occurring within the first 6 months. Because rejection of the cardiac allograft is not necessarily accompanied by overt clinical signs or symptoms and because the incidence of acute rejection is highest during this time period, endomyocardial biopsies are often performed at regularly scheduled intervals following transplantation. A typical biopsy schedule would be weekly for the first postoperative month, biweekly for the next 2 months, and monthly to bimonthly through the remainder of the first post-transplant year. Nonspecific symptoms, including low-grade fever, malaise, mild reduction in exercise capacity, heart failure, or atrial arrhythmias may also be evident and if present are reflective of a more severe rejection episode.
ANTIBODY-MEDIATED REJECTION

Antibody-mediated rejection (AMR), sometimes referred to as vascular or humoral rejection, is characterized by the presence of antibodies directed against HLA antigens present on the donor vascular endothelium. It can be characterized by capillary deposition of immunoglobulins, complement, and fibrinogen on immunofluorescence staining. Circulating immune complexes often precede humoral rejection. This form of rejection is less common than cellular rejection and generally occurs in the first 3 months after transplantation. It is associated with an increased fatality rate and appears to be more common when antilymphocyte antibodies are used for rejection prophylaxis. An increased risk of humoral rejection is associated with female gender, elevated PRA, cytomegalovirus seropositivity, a positive crossmatch, and prior sensitization to OKT3 (muromonab CD3). Strategies to reverse humoral rejection include plasmapheresis, often in combination with intravenous immunoglobulin, high-dose intravenous corticosteroids, antithymocyte globulin, cyclophosphamide, rituximab, and mycophenolate mofetil.

CHRONIC REJECTION

Chronic rejection is a major cause of graft loss. It presents as a slow and indolent form of acute cellular rejection, in which the interaction of the humoral immune system and antibodies against the vascular endothelium appear to play a role. Persistent perivascular and interstitial inflammation is a common finding in kidney, liver, and heart transplantation. As a result of the complex interaction of multiple drugs and diseases over time, it is difficult to delineate the true nature of chronic rejection. Unlike acute rejection, chronic rejection is not reversible with any immunosuppressive agents currently available.

Kidney

Advances in the management of acute rejection during the last decade have increased the duration of functioning grafts from living and cadaveric donors by more than 70%. Chronic allograft nephropathy remains the most common cause of graft loss in the late post-transplantation period (>1 year). The histopathologic characteristics of chronic allograft nephropathy include vascular intimal hyperplasia, tubular atrophy, interstitial fibrosis, and chronic glomerulopathy. Structural changes are seen in as many as 40% of kidney transplantation patients 1 year after transplantation and may present as early as 3 months. Hypertension, proteinuria, and a progressive decline in renal function represent the classic clinical triad of chronic allograft nephropathy. Factors that contribute to the development of chronic allograft nephropathy include calcineurin inhibitor nephrotoxicity, polyomavirus infection, hypertension, donor-related factors including ischemia time and undetected kidney disease in the donor kidney, and recurrence of the primary kidney disease in the recipient.

Liver

Approximately 3 to 5% of transplant livers are affected by chronic rejection, which is characterized by an obliterative arteriopathy and the gradual loss of bile ducts, often referred to as the vanishing bile duct syndrome. Initially patients experience an asymptomatic rise in the alkaline phosphatase and γ-glutamyl transpeptidase. As levels of bilirubin increase, patients become jaundiced and may experience itching.

Heart

Cardiac allograft vasculopathy, characterized by accelerated intimal thickening or development of atherosclerotic plaques, is the leading cause of graft failure and death in heart transplant recipients.

TREATMENT

Immunosuppression

**DESIRED OUTCOME**

Immediately following surgery, the primary goal of therapy is to prevent hyperacute and acute rejection. The high doses of immunosuppressants required to achieve this goal, if maintained long term, may result in serious complications such as nephrotoxicity, infection, thrombocytopenia, and drug-induced diabetes. Therefore rapid dosage reductions are frequently used to minimize these effects. Transplant immunosuppression must be balanced to optimize both graft and patient survival.

**GENERAL APPROACH TO TREATMENT**

1. A multidrug approach is rational from an immunomechanistic viewpoint because the many agents have overlapping and potentially synergistic mechanisms of action. Furthermore, the use of a multidrug immunosuppression regimen may allow the use of lower doses of individual agents, thus reducing the severity of dose-related adverse effects (Fig. 98–2). The protocols and individual drug regimens tend to be medical center specific. Although induction therapy may not be uniformly used, in almost every setting, patients receive IV methylprednisolone intraoperatively. Patients may also receive a descending dose of methylprednisolone over the first 5 to 7 postoperative days before beginning oral prednisone. Protocols generally combine a drug from two or three of the following classes: calcineurin inhibitors, antimetabolites or proliferation signal inhibitors, and corticosteroids.

If rejection is suspected, a biopsy can be done for definitive diagnosis or the patient may be empirically treated for rejection. Empiric treatment generally involves administration of high-dose corticosteroids, usually 500 to 1,000 mg of methylprednisolone intravenously for one to three doses. If signs and symptoms of rejection are resolved with empiric therapy, the maintenance immunosuppressive regimen is generally modified to provide a greater level of overall immunosuppression. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection with polyclonal and monoclonal antibodies being reserved for moderate to severe rejections or those that have not responded to a course of corticosteroids.

**Induction Therapy**

Induction therapy involves the use of a high level of immunosuppression, at the time of transplantation, with or without the immediate
introduction of cyclosporine or tacrolimus (see Fig. 98–2). Induction therapy consists of one of two perioperative immunosuppressive strategies: (a) the provision of a highly intense level of immunosuppression, often on the basis of patient-specific risk factors such as age and race, or (b) the use of antibody therapy to provide enough immunosuppression to delay the initiation of therapy with the nephrotoxic calcineurin inhibitors. The rationale for delayed calcineurin inhibitor administration varies slightly depending on the type of transplant. In renal transplantation, the newly transplanted kidney is very susceptible to nephrotoxic injury, whereas in liver and heart transplantation, the idea is to protect patients with preexisting renal insufficiency from further insults during the perioperative period. Additionally, calcineurin inhibitor dosage adjustment to maintain target concentrations may be difficult in the perioperative period secondary to fluctuation of gastrointestinal motility and enteral intake.

### Acute Rejection

The primary goal of acute rejection therapy is to minimize the intensity of the immune response and prevent irreversible injury to the allograft. The available options include (a) increasing the doses of current immunosuppressive drugs, (b) “pulse” corticosteroids with subsequent dose taper, (c) addition of another immunosuppressant indefinitely, or (d) short-term treatment with a polyclonal or monoclonal antibody. The treatment of acute rejection almost always begins with “pulse” corticosteroid therapy for several days (oral or intravenously). Recent data in renal transplantation indicate, however, that African Americans do not respond as well to corticosteroids; thus antithymocyte globulin may be preferable for this patient population.

Cytolytic agents are often reserved for those with corticosteroid-resistant rejection, signs of hemodynamic compromise (heart), or more severe rejections. Other innovative forms of therapy for persistent or intractable rejection have been investigated, including mycophenolate mofetil, tacrolimus, low-dose methotrexate, sirolimus, total lymphoid irradiation, and plasmapheresis and intravenous immunoglobulin. Prophylactic agents such as valganciclovir, nystatin, trimethoprim-sulfamethoxazole, H₂-receptor antagonists or proton-pump inhibitors, and/or antacids may be added to minimize adverse effects associated with these intensive immunosuppression regimens.
Maintenance Therapy
The goal of maintenance immunosuppression is to prevent acute and chronic rejection while minimizing drug-related toxicity. As patients progress through the post-transplant course, the risk of acute rejection decreases, thus allowing the clinician to gradually reduce the doses of immunosuppressants or in some cases totally withdraw them over a period of 6 to 12 months. Transplant organ and type (cadaveric versus living-donor), the degree of HLA mismatch, time after transplantation, post-transplantation complications (including the number of acute rejections), previous immunosuppressive adverse reactions, compliance, and financial considerations are among the patient-specific factors considered in individualizing maintenance immunosuppression. Calcineurin inhibitors are generally a central component in most maintenance regimens, although calcineurin inhibitor–free immunosuppression remains a future goal because of the significant nephrotoxicity associated with these agents. Ideally, immunosuppression should be optimized to prevent acute rejection episodes and minimize the occurrence of chronic rejection.

CALCINEURIN INHIBITORS
Cyclosporine and tacrolimus are the two calcineurin inhibitors (CIs) currently used for most solid-organ transplant recipients. With the exception of heart transplant recipients (59%), more than 80% of transplant recipients receive tacrolimus as part of their immunosuppressive regimen.1

Although calcineurin inhibitors are the mainstay of immunosuppressive protocols, some clinicians attempt to use calcineurin inhibitor–sparing protocols to avoid the significant adverse effects associated with calcineurin inhibitors. Others will delay the initiation of calcineurin inhibitors to avoid the dose-related adverse effects associated with their use during the early post-transplantation period.

Pharmacology/Mechanism of Action
Calcineurin inhibitors block T-cell proliferation by inhibiting the production of IL-2 and other cytokines by T cells (see Fig. 98–1). Cyclosporine and tacrolimus bind to unique cytoplasmic immunophilins cyclophilin and FK-binding protein-12 (FKBP12), respectively. The drug–immunophilin complex inhibits the action of calcineurin, an enzyme that activates the nuclear factor of activated T cells, which is, in turn, responsible for the transcription of several key cytokines necessary for T-cell activity, including IL-2. IL-2 is a potent growth factor for T cells and ultimately is responsible for activation and clonal expansion.

Pharmacokinetics
The calcineurin inhibitors are highly lipophilic compounds, with variable but generally low bioavailability of approximately 30% (range: 5% to 60%). Unlike tacrolimus, cyclosporine depends on bile for intestinal absorption, which tends to more intermittent and intrapatient variability. Liver recipients with a T-tube for diversion of bile may thus experience incomplete and erratic absorption of cyclosporine.

Because of the significant variability in absorption of cyclosporine, peak concentrations are reached within 2 to 6 hours of oral administration. To overcome the pharmacokinetic prob-
from cyclosporine to tacrolimus or by proper hygiene in patients who cannot be switched to tacrolimus. Tacrolimus, in contrast, has been reported to cause alopecia, which is usually self-limiting and reversible.

**Calcineurin Inhibitor Nephrotoxicity**

Two types of nephrotoxicity can occur with calcineurin inhibitors. Acute nephrotoxicity is frequently seen early and is dose dependent and reversible, but chronic nephropathy is more common. Clinical manifestations of calcineurin inhibitor nephrotoxicity include elevated serum creatinine and blood urea nitrogen levels, hyperkalemia, hyperuricemia, mild proteinuria, and a decreased fractional excretion of sodium. Calcineurin inhibitor nephrotoxicity is recognized as the leading cause of renal dysfunction following nonrenal solid-organ transplant.

The predominant mechanism for calcineurin inhibitor nephrotoxicity is renal vasoconstriction, primarily of the afferent arteriole, resulting in increased renal vascular resistance, decreased renal blood flow by up to 40%, reduced glomerular filtration rate by up to 30%, and increased proximal tubular sodium reabsorption with a reduction in urinary sodium and potassium excretion. A number of other mechanisms have been implicated, including changes in the renin–angiotensin–aldosterone system, prostaglandin synthesis, nitrous oxide production, sympathetic nervous system activation, and calcium handling.

Measures to reduce calcineurin inhibitor nephrotoxicity include delaying administration immediately postoperatively in patients at high risk for nephrotoxicity (using alternative induction protocols including an IL-2 receptor antagonist or antilymphocyte globulin), monitoring calcineurin inhibitor trough blood levels and reducing the calcineurin inhibitor dosage if the vasoconstrictive effects are problematic, and avoiding other nephrotoxins (e.g., aminoglycosides, amphotericin B, and nonsteroidal antiinflammatory agents) when possible. Currently, no proven therapies consistently prevent or reverse the nephrotoxic effects of calcineurin inhibitors.

In patients who have received a kidney transplant, it is often difficult to differentiate calcineurin inhibitor nephrotoxicity from renal allograft rejection. Because the clinical features of acute renal allograft rejection and calcineurin inhibitor nephrotoxicity may overlap considerably, a renal biopsy is necessary to differentiate the two (Table 98–5). However, differentiating between chronic renal allograft rejection and calcineurin inhibitor nephrotoxicity may be more difficult because, in addition to clinical signs and symptoms, biopsy findings may also be similar.

**Drug–Drug and Drug–Food Interactions**

Drug interactions occur frequently with the calcineurin inhibitors because they are substrates for CYP3A4 and P-glycoprotein. Inhibitors of CYP3A4, such as diltiazem or erythromycin, can increase drug concentrations up to 82%, whereas drugs that induce CYP3A4 activity, such as phenytoin or rifampin, can decrease drug concentrations by 50%. Some have taken advantage of these interactions by routinely prescribing CYP3A4 inhibitors to decrease drug concentrations by 50%. Some have taken advantage of these interactions by routinely prescribing CYP3A4 inhibitors to decrease drug concentrations by 50%.

Inhibitors of CYP3A4, such as diltiazem or erythromycin, can increase drug concentrations up to 82%, whereas drugs that induce CYP3A4 activity, such as phenytoin or rifampin, can decrease drug concentrations by 50%. Some have taken advantage of these interactions by routinely prescribing CYP3A4 inhibitors to reduce the dosage and cost of calcineurin inhibitor therapy while maintaining the same therapeutic concentrations. This strategy seems more beneficial with cyclosporine than with tacrolimus. While in vitro data suggest that drugs that increase the pH of the GI tract, such as magnesium-, aluminum-, or calcium-containing antacids, sodium bicarbonate, and magnesium oxide, can cause a pH-mediated degradation of tacrolimus by physically adsorbing tacrolimus in the GI tract, this has not been borne out in clinical studies. Some clinicians suggest separating such compounds from tacrolimus administration by at least 2 hours to avoid any potential interaction.

Cyclosporine, and to a lesser extent, tacrolimus, are inhibitors of CYP3A4. The inhibitory effects of cyclosporine and tacrolimus on CYP3A4 can be seen with weaker substrates, such as the HMG-CoA reductase inhibitors (“statins”). Concomitant administration of a calcineurin inhibitor with an HMG-CoA reductase inhibitor results in an increase in the HMG-CoA reductase inhibitor levels, which increases the risk of HMG-CoA reductase inhibitor adverse effects, most notably myopathy. Patients should be monitored for clinical signs of myopathy when receiving HMG-CoA reductase inhibitors in combination with cyclosporine and tacrolimus.

Cr, creatinine; CSA, cyclosporine; TAC, tacrolimus.
Consistency in administration of the calcineurin inhibitors with regard to meals and food intake is important to sustain an effective concentration time profile. High-fat meals can enhance both plasma clearance and the volume of distribution of cyclosporine by more than 60%. Food reduces the rate and extent of tacrolimus absorption, and a high-fat meal may further delay gastric emptying and reduce the maximum achieved serum concentration \( C_{\text{max}} \), and the area under the concentration–time curve (AUC). Furocoumarins, such as quercetin, naringin, and bergamottin, found in grapefruit juice, are potent inhibitors of CYP3A4 and have increased both cyclosporine and tacrolimus concentrations significantly. The AUC and \( C_{\text{max}} \) of cyclosporine have been reported to be increased by more than 55% and 35%, respectively.17

**Dosing and Administration**

Initial oral cyclosporine doses range from 8 to 18 mg/kg per day administered every 12 hours. Higher doses of cyclosporine are used more commonly in two-drug regimens, whereas lower doses are part of triple-drug regimens. Oral tacrolimus doses range from 0.1 to 0.3 mg/kg per day given every 12 hours. If oral administration is not possible, both drugs can be administered intravenously at one third the oral dosage, to account for first-pass metabolism. A once-daily formulation of tacrolimus is currently available in Canada and Europe. After mg:mg conversion based on total daily dose, about one third of patients required downward gastric emptying and reduce the maximum achieved serum concentration \( C_{\text{max}} \), and the area under the concentration–time curve (AUC). Furocoumarins, such as quercetin, naringin, and bergamottin, found in grapefruit juice, are potent inhibitors of CYP3A4 and have increased both cyclosporine and tacrolimus concentrations significantly. The AUC and \( C_{\text{max}} \) of cyclosporine have been reported to be increased by more than 55% and 35%, respectively.17

**Therapeutic Drug Monitoring**

Calcineurin inhibitor serum concentrations are measured routinely in an attempt to optimize therapy (Table 98–7). The most common and practical method for monitoring calcineurin inhibitors is by measuring trough blood concentrations. Radioimmunoassay (RIA) and fluorescence polarization immunoassay are the most commonly used methods to measure cyclosporine concentrations. Tacrolimus concentrations are most commonly measured by microparticle enzyme immunoassays or enzyme-linked immunoassays. Both drugs can be measured by high-performance liquid chromatography (HPLC), which is recognized as the reference procedure. Therapeutic target ranges are assay specific because some quantitate parent plus metabolite concentration, while others only measure the parent compound. Thus, the target concentrations will be lower for the specific assays (HPLC) compared with nonspecific assays (RIA and microparticle enzyme immunoassays) by approximately 20% to 25%. The specific goal level for both drugs is dependent on transplant type, time after transplantation, concomitant immunosuppression, and transplantation center. One review of the role of tacrolimus in renal transplantation suggests that target 12-hour whole blood concentrations for tacrolimus are 15 to 20 ng/mL (15 to 20 μg/L; 18.6 to 24.8 nmol/L) (0 to 1 month after transplantation), 10 to 15 ng/mL (10 to 15 μg/L; 12.4 to 18.6 nmol/L) (1 to 3 months after transplantation), and 5 to 12 ng/mL (5 to 12 μg/L; 6.2 to 14.9 nmol/L) (>3 months after transplantation). Serum drug concentrations should be measured frequently (daily or three times per week) following initiation of the drug and during the stabilization period after transplantation. As the time increases after transplantation, serum concentrations are measured less frequently, usually monthly.

Studies have revealed lack of predictive value of trough cyclosporine concentrations and rejection. Alternative strategies, including AUC and peak concentration, have been suggested to better correlate with rejection. Limited sampling techniques using two to five blood samples within the first 4 hours after an oral dose have been used. AUC levels > 4,400 mcg/L (> 3361 nmol/L) per hour correlate with a reduction in rejection. Some transplantation

centers have adopted this strategy to manage cyclosporine levels because of the convenience of a single blood sample. The suggested therapeutic range for \( C_s \) cyclosporine levels is 1,500 to 2,000 ng/mL (1,500 to 2,000 μg/L; 1248 to 1664 nmol/L) for the first few months after transplant and 700 to 900 ng/mL (700 to 900 μg/L; 582 to 749 nmol/L) after 6 to 12 months.39 The predictive value of trough concentrations and rejection is also being questioned with tacrolimus. As a result, pharmacokinetic profiling with AUC and peak concentrations to determine alternative monitoring strategies are also being explored with tacrolimus.39

### CORTICOSTEROIDS

Corticosteroids have been used since the beginning of the modern transplantation era. Despite their many adverse events, they continue to be a cornerstone of immunosuppression regimens in many transplant centers, with 40 to 70% of liver and kidney transplant patients, respectively, receiving corticosteroids at the time of hospital discharge.1 The most commonly used corticosteroids in transplantation are methylprednisolone and prednisone.

**Pharmacology/ Mechanism of Action**

Corticosteroids block cytokine activation by binding to corticosteroid response elements, thereby inhibiting IL-1, IL-2, IL-3, IL-6, \( \gamma \)-interferon, and tumor necrosis factor-\( \alpha \) synthesis (see Fig. 98–1). Additionally, corticosteroids interfere with cell migration, recognition, and cytotoxic effector mechanisms.40

**Pharmacokinetics**

Prednisone is converted to active prednisolone in the body and has multiple effects on the immune system. Prednisone is very well absorbed from the GI tract and has a long biologic half-life, permitting daily administration.

**Efficacy**

Animal models of transplantation in the 1950s and 1960s used corticosteroids empirically in combination with azathioprine. Corticosteroids subsequently became a part of the immunosuppressive regimens used in the first human transplantations41 and continue to be used in immunosuppressive protocols today. The efficacy of corticosteroids is irrefutable based on the decades of clinical experience. Systematic studies comparing corticosteroid-free immunosuppressive agent combinations with conventional therapy are difficult to perform because of the hundreds of potential combinations that now exist. However, recent studies of corticosteroid-free immunosuppressive agent combinations with newer, more specific immunosuppressants suggest that corticosteroids may in the future have less of a role in maintenance immunosuppression.21,22

**Adverse Effects**

Adverse effects of prednisone that occur in more than 10% of patients include increased appetite, insomnia, indigestion (bitter taste), and mood changes. Side effects that occur less often but which are seen with high doses or prolonged therapy include cataracts, hyperglycemia, hirsutism, bruising, acne, sodium and water retention, hypertension, bone growth suppression, and ulcerative esophagitis (see Table 98–4).

**Drug–Drug and Drug–Food Interactions**

Barbiturates, phenytoin, and rifampin induce hepatic metabolism of prednisone and thus decrease the effectiveness of prednisone. Prednisone decreases the effectiveness of vaccines and toxoids.40

**Dosing and Administration**

An intravenous corticosteroid, commonly high-dose methylprednisolone, is given at the time of transplantation. The dose of methylprednisolone is tapered rapidly and discontinued within days, and oral prednisone is initiated. Prednisone doses are tapered progressively over time, depending on the type of additional immunosuppression and organ function. It is preferable to administer corticosteroids between 7 AM and 8 AM to mimic the body’s diurnal release of cortisol. While conversion to alternate-day regimens or complete withdrawal of prednisone in patients with stable post-transplantation courses has been used with success in some transplantation centers, corticosteroids are often continued for the entire life of the functional graft. The adverse effects of corticosteroids are summarized in Table 98–4.

The first-line therapy for the treatment of acute graft rejection is high-dose intravenous methylprednisolone (250 to 1,000 mg) daily for 3 days or oral prednisone (200 mg). Doses of oral prednisone are then tapered over 5 days to 20 mg/day. Prednisone should be taken with food to minimize GI upset. It is becoming a frequent practice to taper prednisone, with the goal of discontinuation over a period of months. Corticosteroids should never be discontinued abruptly; tapering should be gradual because of suppression of the hypothalamic–pituitary–adrenal axis. Corticosteroids slow the growth rates in children, prompting clinicians to use alternate-day dosing or to withhold corticosteroids until rejection occurs.

### ANTIMETABOLITES

Antimetabolites have been used since the early days of transplantation because they prevent proliferation of lymphocytes. Azathioprine, long considered a part of the “gold standard” regimen with cyclosporine and corticosteroids, has largely been supplanted by mycophenolic acid derivatives as they are more specific in their effects on lymphocytes and have fewer side effects.

**Mycophenolate**

Mycophenolic acid (MPA) was first isolated from the *Penicillium glaucum* mold. Two formulations of MPA are currently available in the United States: mycophenolate mofetil is the morpholinoethyl ester of MPA, whereas mycophenolate sodium is available as an enteric-coated formulation of the sodium salt of MPA.

**Pharmacology/ Mechanism of Action**

The immunosuppressive effect of MPA is exerted through noncompetitive binding to inosine monophosphate dehydrogenase, the key enzyme responsible for guanosine nucleotide synthesis via the de novo pathway. Inhibition of inosine monophosphate dehydrogenase results in decreased nucleotide synthesis and diminished DNA polymerase activity, ultimately reducing lymphocyte proliferation.42 The actions of MPA are more specific for T and B cells, which use only the de novo pathway for nucleotide synthesis (see Fig. 98–1). Other cells within the body have a salvage pathway by which they can synthesize nucleotides, making them less susceptible to the actions of MPA and thereby reducing, but not eliminating, the potential for the hematologic adverse effects seen with azathioprine. In addition to decreasing lymphocyte proliferation, MPA may also downregulate activation of lymphocytes.43

**Pharmacokinetics**

Because MPA is unstable in an acidic environment, mycophenolate mofetil acts as a prodrug that is readily absorbed from the GI tract, after which it is rapidly and completely converted to MPA by first-pass metabolism. The enteric coating of mycophenolate sodium protects MPA from the acidic gastric pH and allows for MPA to be released directly into the small intestine for absorption. The absolute bioavailability of MPA when delivered...
from mycophenolate mofetil and mycophenolate sodium is 94% and 72%, respectively. Peak concentrations of MPA are reached within 1 hour following administration of either preparation.

A total of 97% of MPA is bound to albumin in the blood. MPA is eliminated by the kidney and also undergoes glucuronidation in the liver to an inactive glucuronide metabolite (MPAG) that is excreted in the bile and urine. Enterohepatic cycling of MPAG can lead to deconjugation, thereby recirculating MPA into the bloodstream. The half-life of MPA is 18 hours.

**Efficacy** Currently, mycophenolate mofetil is approved for use in kidney, liver, and heart transplantations. Mycophenolate sodium was approved in 2004 for use in kidney transplantsations only. Early studies comparing mycophenolate to azathioprine in patients receiving cyclosporine and corticosteroids demonstrated a statistically significant improvement in patient and graft survival at 1 and 3 years. Subsequent studies have confirmed the efficacy of mycophenolate combined with tacrolimus. Mycophenolate has also demonstrated efficacy in the treatment of acute rejection.

Mycophenolic acid derivatives are a key component of calcineurin inhibitor–sparing protocols. Although mycophenolate monotherapy has been investigated, patients experienced an unacceptable increase in rejection. Combination of mycophenolate with sirolimus, on the other hand, resulted in improved renal function with no change in acute rejection and patient and graft survival.

**Adverse Effects** Unlike cyclosporine and tacrolimus, MPA is not associated with nephrotoxicity, neurotoxicity, or hypertension. The most common side effects are related to the GI tract, including nausea, vomiting, diarrhea, and abdominal pain (see Table 98–4), which occur with similar frequency during intravenous and oral therapy. Strategies to reduce GI symptoms include dose reduction, division of the total daily dose into three or four doses, administration with food, or titration upward from lower doses during initial therapy. Mycophenolate also has hematologic effects, such as leukopenia and anemia, particularly with higher doses. Recently, the rare but serious adverse events of progressive multifocal leukoencephalopathy (PML) and pure red cell aplasia have been reported. Because peripheral intravenous mycophenolate administration is associated with local edema and inflammation, central venous administration may be the preferred route.

**Drug–Drug and Drug–Food Interactions** Food has no effect on MPA AUC, but it delays the absorption and decreases MPA C_{ss} by 40% and 33% when mycophenolate mofetil and mycophenolate sodium, respectively, are administered. Administration with aluminum- and magnesium-containing antacids or cholestyramine significantly decreases the AUC of MPA and should be avoided. It has been suggested that administration of iron may produce similar results, but this has not been tested.

Acyclovir, commonly used in renal transplant recipients for the treatment and prevention of viral infections, competes with MPAG for renal tubular secretion. AUCs of both entities are increased with concomitant acyclovir and mycophenolate administration. No pharmacokinetic interaction with other antiviral agents has been demonstrated, but, there is potential for additive pharmacodynamic effects such as bone marrow suppression.

Decreased MPA trough concentrations have been reported when mycophenolate is administered with cyclosporine compared with those achieved when mycophenolate is given with tacrolimus or sirolimus. This interaction is most likely a result of cyclosporine interference with the enterohepatic recycling of MPAG, which results in decreased MPA concentrations. To achieve equivalent MPA and MPAG serum concentrations, it may be necessary to administer higher doses of mycophenolate with cyclosporine compared to tacrolimus.

**Dosing and Administration** Mycophenolate mofetil is currently available in both oral and intravenous formulations. Although intravenous administration of equal doses closely mimics oral administration, the two cannot be considered bioequivalent. Mycophenolate sodium is only available as an oral formulation. To optimize immunosuppression and minimize adverse effects, mycophenolate is administered in two divided doses given every 12 hours. The total daily dose for kidney and liver transplants is 2 g/day for mycophenolate mofetil and 1.44 g/day for mycophenolate sodium. A higher level of immunosuppression is required for heart transplants; thus for these patients a total daily dose of 3 g/day for mycophenolate mofetil and 2.16 g/day for mycophenolate sodium is recommended. The recommended pediatric dose is 600 mg/m² for mycophenolate mofetil and 400 mg/m² for mycophenolate sodium, in two divided doses.

While an increasing body of literature exists, the routine therapeutic drug monitoring of mycophenolic acid remains controversial. Plasma appears to be the most appropriate medium in which to measure MPA for therapeutic drug monitoring. Numerous studies have demonstrated a relationship between plasma MPA concentrations and improved clinical outcomes in patients receiving concomitant CsA and corticosteroids. Patients with trough MPA levels between 1.0 and 3.5 mcg/mL (1.0–3.5 mg/L; 3.1 to 10.9 micromol/L) experienced fewer significant complications. Free (fMPA) concentrations as opposed to total MPA concentrations have been suggested as the relevant measure, especially in patients with liver disease, hypoalbuminemia, and severe infection. Trough concentrations may not be accurate in predicting total drug exposure during a 12-hour interval and thus AUC monitoring has been proposed as the most appropriate measure of MPA drug exposure to predict therapeutic outcomes. Better outcomes are associated with MPA AUC levels of greater than 42.8 mcg/mL (42.8 mg/L; 134 micromol/L) per hour (by HPLC), although a reference range of 30 to 60 mcg/mL (30 to 60 mg/L; 94 to 188 micromol/L) per hour has been proposed. The correlation between MPA AUC levels and adverse effects is low. Further studies are required to determine the best means to evaluate MPA levels, the acceptable targets for each, and the appropriate strategy to monitor MPA levels.

**Azathioprine** Azathioprine, a prodrug for 6-mercaptopurine (6-MP), has been used as an immunosuppressant in combination with corticosteroids since the earliest days of the modern transplantation era. It is associated with substantial toxicities, however, and its use has dramatically declined with the availability of newer immunosuppressants.

**Pharmacology/Mechanism of Action** Azathioprine is an inactive compound that is converted rapidly to 6-MP in the blood and is subsequently metabolized by three different enzymes. Xanthine oxidase, found in the liver and GI tract, converts 6-MP to the inactive final product, 6-thiouric acid. Thiopurine S-methyltransferase, found in hematopoietic tissues and red blood cells, methylates 6-MP to an inactive product, 6-methylmercaptopurine. Finally, hypoxanthine-guanine phosphoribosyltransferase is the first step responsible for converting 6-MP to 6-thioguanine nucleotides (6-TGNs), the active metabolites, which are incorporated into nucleic acids, ultimately disrupting both the salvage and de novo pathways of DNA, RNA, and protein synthesis. This process is toxic to the cell and renders the cell unable to proliferate (see Fig. 98–1). Eventually, 6-TGNs are catabolized by xanthine oxidase and thiopurine S-methyltransferase to inactive products.

**Pharmacokinetics** Oral bioavailability of azathioprine is approximately 40%. Metabolism of 6-MP is primarily by xanthine oxidase to inactive metabolites, which are excreted by the kidneys. The half-life of azathioprine, the parent compound, is very short,
approximately 12 minutes. The half-life of 6-MP is longer, ranging from 0.7 to 3 hours. However, it is the activity of the 6-TGNs that determines the pharmacodynamic half-life of the drug. The half-life of 6-TGNs has been estimated to be 9 days.\(^{50}\)

**Adverse Effects** Dose-limiting adverse effects of azathioprine are often hematologic (see **Table 98–4**). Leukopenia, anemia, and thrombocytopenia can occur within the first few weeks of therapy and can be managed by dose reduction or discontinuation of azathioprine. Other common adverse effects include nausea and vomiting, which can be minimized by taking azathioprine with food. Alopecia, hepatotoxicity, and pancreatitis are less common adverse effects of azathioprine and are reversible on dose reduction or discontinuation.

**Drug–Drug and Drug–Food Interactions** The xanthine oxidase inhibitor allopurinol can increase azathioprine and 6-MP concentrations by as much as fourfold. The metabolic pathways shift to favor production of 6-TGNs, which ultimately results in increased bone marrow suppression and pancytopenia. Doses of azathioprine should be reduced by 50% to 75% when allopurinol is added. Additional clinically significant drug interactions include other bone marrow–suppressing agents such as ganciclovir, trimethoprim-sulfamethoxazole, and sirolimus, and other drugs that irritate the GI tract.

**Dosing and Administration** Initial doses of azathioprine are 3 to 5 mg/kg per day intravenously or orally. Individualization to maintain the white blood cell count between 3,500 and 6,000 cells/mm\(^3\) (3.5 and 6.0 \(\times\) 10\(^3\)/L) may be accomplished in some with doses as low as 0.25 mg/kg per day.\(^{11}\) Patients are often instructed to take azathioprine in the evening when initiating or titrating therapy to allow for dose adjustments based on morning determinations of their white blood cell count.

### MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

Two mammalian target of rapamycin (mTOR) inhibitors have been approved in the United States for use in transplantation. Sirolimus, also known as rapamycin, is an immunosuppressive macrolide antibiotic that is structurally similar to tacrolimus, and is effective in reducing the risk of acute rejection. Sirolimus is thought to have potential to reduce chronic rejection, but this remains to be proven. Everolimus was approved in 2009.

**Pharmacology/Mechanism of Action** Sirolimus and everolimus both bind to FKBP12, forming a complex that binds to mTOR, which inhibits the response to cytokines (see Fig. 98–1). IL-2 stimulates mTOR to activate kinases that ultimately advance the cell cycle from G1 to the S phase. Thus they reduce T-cell proliferation by inhibiting the cellular response to IL-2 and progression of the cell cycle. To this end, this class is also referred to as proliferation signal inhibitors.\(^{51,52}\)

**Pharmacokinetics** Bioavailability after oral administration is low for both, only 15–16%, with peak concentrations being reached within 1 to 2 hours for sirolimus and 0.5–4 hours for everolimus.\(^{51,52}\) Both have large volumes of distribution, 5.6–16.7 L/kg for sirolimus and about 110 L for everolimus. Both are metabolized primarily by CYP3A4 both in the gut and in the liver. Likewise, both are also substrates for P-glycoprotein. The half-life for sirolimus is reported to be 60 hours but can be as long as 110 hours in patients with liver dysfunction, while that of everolimus is much shorter, 18–35 hours.\(^{51,52}\)

**Efficacy** Sirolimus is only approved for the prevention of rejection in kidney transplant recipients when given in combination with corticosteroids and cyclosporine or after withdrawal of cyclosporine in patients with low to moderate immunologic risk. Sirolimus has also been demonstrated to be effective in combination with tacrolimus or mycophenolate in kidney transplants, with patient survival rates >99% and graft survival rates >96%.\(^{51}\) Combination therapy with sirolimus and mycophenolate can be used to avoid the use of calcineurin inhibitors and decrease the risk of nephrotoxicity. Everolimus was approved for use in renal transplantation in combination with basiliximab, cyclosporine, and corticosteroids.

Two Phase III trials evaluated the use of sirolimus in kidney transplants. All patients in both studies received cyclosporine and corticosteroids and were randomly assigned to one of three groups: (a) sirolimus in a fixed dose—a 6-mg loading dose followed by 2 mg daily; (b) a 15-mg loading dose followed by 5 mg daily; or (c) azathioprine in the U.S. trial or placebo in the global trial. The results of both studies showed similar patient and graft survival in all groups at 12 months but lower rates of acute rejection in the sirolimus arms compared with azathioprine and placebo.\(^{51}\)

Early cyclosporine withdrawal has been studied in patients receiving sirolimus-based immunosuppressive protocols. Patients receiving sirolimus who did not have a recent or severe rejection episode and adequate renal function 3 months after transplant were enrolled. Patients were randomly assigned to continue triple-therapy with sirolimus (adjusted to trough concentrations of greater than 5 ng/mL), cyclosporine, and corticosteroids or double-therapy with sirolimus (adjusted to trough concentrations of 20 to 30 ng/mL) and corticosteroids. Rejection occurred in 5.6% of patients after discontinuation of cyclosporine, with no difference in graft survival. Long-term follow-up (2 years) showed improved renal function and blood pressure without an increase in acute rejection or graft loss in patients who discontinued cyclosporine.\(^{51}\)

Everolimus in combination with reduced doses of cyclosporine (target 100–200 ng/mL for the first month post transplant) and steroids was comparable to mycophenolic acid (1.44 g/day) in combination with standard cyclosporine doses (target 100–200 ng/mL in the first month) and steroids in terms of biopsy-proved rejection, graft loss, or death. There was no difference in estimated GFR at 12 months. Similarly, a trial of high-dose everolimus/low-dose CSA (target 8–12 ng/mL vs. 3–8 ng/mL) showed no difference in 6- and 12-month GFR between the two groups despite differences in CSA exposure.\(^{51}\)

Currently, because the safety and efficacy of sirolimus and everolimus have not been established in liver or lung transplants, it is recommended that their use be avoided in these populations immediately following transplant. In contrast, limited data on the use of sirolimus in heart transplantation indicate benefit in reversing acute rejection in patients who do not respond to antilymphocyte therapy.\(^{51}\) Furthermore, mTOR inhibitors may slow the progression of vasculopathy, which may have an impact on chronic rejection and long-term patient survival after heart transplantation.\(^{19}\)

**Adverse Effects** Both everolimus and sirolimus are associated with dose-related myelosuppression. Thrombocytopenia is usually seen within the first 2 weeks of sirolimus therapy but generally improves with continued treatment; leukopenia and anemia are also typically transient.\(^{51,52}\) Sirolimus trough serum concentrations greater than 15 ng/mL have been correlated with thrombocytopenia and leukopenia.\(^{51}\) Hypercholesterolemia and hypertriglyceridemia are also common in patients receiving everolimus or sirolimus. It is postulated that the mechanism of this adverse effect is related to an overproduction of lipoproteins or inhibition of lipoprotein lipase. Peak cholesterol and triglyceride levels are often seen within 3 months of sirolimus initiation but usually decrease after 1 year of therapy and can be managed by reducing the dose, discontinuing sirolimus, or initiating therapy with an HMG-CoA reductase inhibitor or fibric acid derivative. One study suggests that the
dyslipidemia associated with sirolimus is not a major risk factor for early cardiovascular complications following kidney transplantation.54 Delayed wound healing and dehiscence could be a result of inhibition of smooth muscle proliferation and intimal thickening.51 Mouth ulcers also have been reported with sirolimus, more commonly with the oral solution, possibly as a direct effect of the drug or secondary to activation of herpes simplex virus.55 Reversible interstitial pneumonitis has been described in kidney, liver, and heart–lung transplantation recipients.51 Other adverse effects reported with sirolimus include increased liver enzymes, hypertension, rash, acne, diarrhea, and arthralgia (see Table 98–4).

### Drug–Drug and Drug–Food Interactions

The major metabolic path for everolimus and sirolimus is CYP3A4; thus, the drug interactions mediated by induction or inhibition of the CYP3A4 enzyme system are similar to those seen with cyclosporine and tacrolimus (see Table 98–5). Administration of the microemulsion formulation of cyclosporine with sirolimus significantly increases the AUC and trough sirolimus levels. The same is not seen with the standard formulation of cyclosporine. Conversely, cyclosporine concentrations and AUC are also increased when it is given concomitantly with sirolimus. The mechanism is proposed to be competitive binding to CYP3A4 and P-glycoprotein.51,52 It is recommended that patients separate the dose of sirolimus and cyclosporine by 4 hours to minimize the interaction.51 Concomitant administration of tacrolimus does not affect sirolimus levels.51 Although everolimus AUC was increased by the administration of a single dose of cyclosporine modified, no specific recommendations for dose timing are given. It should be expected, however, that any changes in CSA dose may also necessitate a modification of everolimus dose and increased therapeutic drug monitoring is indicated.52

As with cyclosporine and tacrolimus, grapefruit juice increases sirolimus levels. Administration of sirolimus with a high-fat meal is associated with a delayed rate of absorption, decreased Cmax, and increased AUC, indicating an increased drug exposure, whereas the half-life remains unchanged.51 Conversely, administration of everolimus with a high-fat meal decreases both Cmax and AUC.51

### Dosing and Administration

A fixed sirolimus dosing regimen is approved for concomitant use with cyclosporine that includes a loading dose of 6 or 15 mg followed by 2 or 5 mg daily, respectively. Therapeutic monitoring of sirolimus is advocated using whole-blood concentrations measured by HPLC, which is specific for the parent compound (see Table 98–7). For everolimus a starting dose of 0.75 mg twice daily is indicated in regimens that contain cyclosporine, corticosteroids, and basiliximab. Target concentrations are 3—8 ng/ml.

### Antibody Agents

Both polyclonal and monoclonal antibody preparations are used in transplantation. These agents can also be differentiated by their level of specificity, that is, particular receptor(s), or their downstream effects. In the following text the agents are discussed as those that deplete lymphocytic cell lines (depleting antibodies) and those that generally bind to specific receptors but do not result in depletion of the cell to which they bind.

### DEPLETING ANTIBODIES

#### Antithymocyte Globulin

Two antithymocyte globulins are available in the United States: ATG (Atgam, Pfizer, New York, NY), an equine polyclonal antibody, and RATG (Thymoglobulin, Genzyme, Cambridge, MA), a rabbit polyclonal antibody. The rabbit preparation is less immunogenic and may have other advantages over the equine preparation. Both ATG and RATG are often used as induction therapy to prevent acute rejection. In 2006 40–60% of kidney transplant recipients received RATG induction, for example.1

#### Pharmacology/Mechanism of Action

Because of their polyclonal antibody nature, both ATG and RATG exert their immunosuppressive effect by binding to a wide array of lymphocyte receptors (CD2, CD3, CD4, CD8, CD25, and CD45). Binding of ATG or RATG to the various receptors results in complement-mediated lysis and subsequent lymphocyte depletion. While T cells are the major lymphocytic target for the compounds, other blood cell components such as B cells and other leukocytes are also affected (see Fig. 98–1). Damaged T cells are subsequently removed by the spleen, liver, and lungs.

#### Pharmacokinetics

ATG is poorly distributed into lymphoid tissue and binds primarily to circulating lymphocytes, granulocytes, and platelets. The terminal half-life of ATG is 5.7 days. RATG has a volume of distribution of 0.12 L/kg, and its terminal half-life in renal transplant recipients is significantly longer than ATG at 30 days.56 Peak plasma concentrations are reached after 5 to 7 days of ATG or RATG infusions. Antiequine antibodies can form in up to 78% of patients who are receiving ATG therapy. Similarly, antirabbit antibodies have been reported in up to 68% of patients who are receiving RATG therapy. The effects of preformed antibodies on the efficacy and safety of these preparations have not been studied adequately.

#### Efficacy

ATG and RATG are used most commonly for the treatment of acute allograft rejection or as induction therapy to prevent acute rejection. ATG is currently approved for both indications in kidney transplants. RATG is approved only for the treatment of acute allograft rejection in kidney transplants. Both drugs have been studied extensively for both indications.

Use of RATG as part of quadruple therapy in liver transplantation is associated with similar rates of patient and graft survival and acute rejection compared with dual therapy. In kidney transplant RATG was associated with improved graft survival at 5 years as compared with equine ATG. Quadruple-drug therapy results in similar rates of patient and graft survival and malignancy in heart transplantations, but a significantly lower rate of acute rejection and infection episodes is seen at 1 year compared with triple-drug therapy. Cytomegalovirus (CMV) is an adverse effect of this strategy, but recent data indicate that routine prophylaxis is successful in this setting.57

#### Adverse Effects

Most adverse effects reported with ATG and RATG are related to the lack of specificity for T cells owing to their polyclonal nature. Dose-limiting myelosuppression (leukopenia, anemia, and thrombocytopenia) occurs frequently. Other adverse effects include anaphylaxis, hypotension, hypertension, tachycardia, dyspnea, urticaria, and rash. Serum sickness is seen more frequently with ATG than with RATG. Nephrotoxicity has been reported but is rare in the absence of serum sickness. Infusion-related febrile reactions are most common with the first few doses and can be managed by premedicating the patient with acetaminophen, diphenhydramine, and corticosteroids. Finally, as with any immunosuppressive agent, ATG and RATG are associated with an increased risk of infections, particularly viral infections, and malignancy.

#### Drug–Drug and Drug–Food Interactions

Administration of ATG or RATG can interfere with the immune response to live vaccines, such as varicella vaccine. If a live vaccine is administered within 2 months of receiving one of these immunoglobulins, protection may not be conferred.

#### Dosing and Administration

ATG doses range from 10 to 30 mg/kg per day as a single dose for 7 to 14 days. RATG is a more potent compound and is administered at doses of 1 to 1.5 mg/kg
per day as a single dose for 7 to 14 days for acute rejection or for 5 to 10 days for induction of immunosuppression. Although literature reports now support peripheral administration of both agents, it is recommended that both ATG and RATG be administered through a central line or through a high-flow vein with an in-line 0.22-micron filter over at least 4 hours to minimize phlebitis and thrombosis whenever possible.57,58

**Muromonab-CD3**

**Pharmacology/Mechanism of Action** OKT3 is a murine monoclonal antibody to the CD3 receptor on mature human T cells (see Fig. 98–1). Administration of OKT3 results in both T-cell depletion and functional alteration. Cells reappear after a few days but bear no CD3 receptors. After cessation of OKT3 therapy, T-cell function normalizes in a week.59

**Pharmacokinetics** OKT3 has a volume of distribution of 6.5 L and half-life of about 18 hours. Concentrations above 0.9 mcg/ml (0.9 mg/L) are considered therapeutic. An OKT3 concentration of 0.8 mcg/ml (0.9 mg/L) or greater in combination with a CD3+ T-cell count of <25 cells/ml (<25 x 10^6/L) is also a reasonable therapeutic target. If CD3 levels begin to rise, this may signify the presence of antimurine antibodies antagonizing the actions of OKT3. Administration of mycophenolate mofetil has been suggested to reduce the formation of antimurine antibodies during OKT3 administration. Although T-cell depletion is achieved within minutes of administration, resolution of rejection takes 3 to 4 days.

**Efficacy** OKT3 has been used as induction therapy at doses of 5 mg/day for 7 to 14 days. OKT3 can be used safely and successfully as an acute rejection therapy in patients who have undergone previous OKT3 induction.59 Specifically, these studies confirm that the presence of low anti-OKT3 antibody titers (≤1:100) does not preclude successful retreatment with OKT3 for rejection. Aside from intestinal transplantation, OKT3 is usually reserved for treatment of corticosteroid-resistant rejection.

**Adverse Effects** OKT3 administration is associated with a cytokine release syndrome including fever, chills, rigor, pruritus, and alterations in blood pressure, which is most common with the first dose. Methylprednisolone, acetaminophen, and diphenhydramine are commonly administered as premedications to prevent or minimize the severity of this syndrome. Other adverse effects include capillary leak syndrome and pulmonary edema, especially in fluid-overloaded patients. Aseptic meningitis, another potential complication of OKT3 therapy, warrants discontinuation of OKT3. Other adverse effects include encephalopathy, nephrotoxicity, infection, and post-transplantation lymphoproliferative disorder.40

**Drug-Drug and Drug-Food Interactions** No drug or food interactions have been reported with OKT3.

**Dosing and Administration** OKT3 should be filtered with a 0.2- to 0.22-micron filter and then administered as an intravenous push over 1 minute. The dose of OKT3 is usually 5 mg/day for 5 to 14 days.59 Vital signs should be assessed, particularly during the first few doses, and it is advisable to have a physician present for the first dose. A high proportion of patients treated with OKT3 form antibodies to one of the components of OKT3 and may not be able to receive or adequately respond to retreatment.59 The dosages of other immunosuppressant drugs may be decreased to avoid immunosuppression during OKT3 therapy.

**Alemtuzumab**

Alemtuzumab is approved for use in B-cell chronic lymphocytic leukemia. However, its effects on depleting both T and B lymphocytes make it useful in solid-organ transplants. While alemtuzumab is not FDA approved for solid organ transplantation, it is increasingly recognized as a viable therapeutic option. In 2006 10% of kidney transplant patients received alemtuzumab at the time of transplant.1

**Pharmacology/Mechanism of Action** Alemtuzumab is a humanized monoclonal antibody against the CD52 surface antigen found on both T and B lymphocytes, as well as macrophages, monocytes, eosinophils, and natural killer cells. When alemtuzumab binds to the CD52 surface antigen, antibody-dependent lysis occurs, which removes both T and B lymphocytes from the blood, bone marrow, and organs, resulting in complete lymphocyte depletion.40

**Pharmacokinetics** The pharmacokinetics of alemtuzumab in solid-organ transplantation have not been investigated. Data from patients with B-cell chronic lymphocytic leukemia indicate that the volume of distribution of alemtuzumab after repeated dosing is 0.18 L/kg. The mean half-life after the first 30 mg dose was 11 hours, but increased to 6 days after 12 weeks of therapy. The extrapolation of these data to solid-organ transplantation is difficult because of the differences in dosing strategies (single or double doses in solid-organ transplantation versus weekly to thrice weekly dosing in B-cell chronic lymphocytic leukemia). One or two doses of alemtuzumab result in complete and prolonged lymphocyte depletion. Following administration, B lymphocyte counts return to normal within 3 to 12 months. T lymphocytes, however, remain depressed for as long as 3 years following administration.60,61

**Efficacy** Recent data suggest that alemtuzumab is effective as induction therapy for the prevention of acute rejection in kidney, liver, pancreas, intestinal, and lung transplants.50 Additionally, alemtuzumab has been used to successfully treat acute rejection following transplantation and is effective for corticosteroid- and antibody-resistant rejection.61,62 The most promising role of alemtuzumab in solid-organ transplantation is its use in corticosteroid-sparing protocols, which allow for calcineurin inhibitor monotherapy following transplantation. Tacrolimus appears to be the optimal calcineurin inhibitor to use for monotherapy immunosuppression in patients who receive alemtuzumab induction.

**Adverse Effects** Adverse effects of alemtuzumab are primarily infusion related, hematologic, and infectious. Infusion-related reactions include rigors, hypotension, fever, shortness of breath, bronchospasms, and chills. The potential for developing these reactions can be reduced by administering premedications such as acetaminophen, corticosteroids and diphenhydramine or by administering smaller doses and escalating the dose gradually. Hematologic effects include pancytopenia, neutropenia, thrombocytopenia, and lymphopenia.

**Drug-Drug and Drug-Food Interactions** No drug or food interactions have been reported with alemtuzumab.

**Dosing and Administration** Several dosing regimens have been proposed for alemtuzumab in solid-organ transplantation. The most common dosing strategy for alemtuzumab is 30 mg as a single dose; some centers administer a second dose 1 to 5 days after transplantation.60 Other studied dosing strategies include 0.3 mg/kg per dose, as a single- or multiple-dose regimen, and, finally, two 20-mg doses given on the day of transplantation and the first postoperative day.55

■ NONDEPLETING ANTIBODIES

**Interleukin-2 Receptor Antagonists**

Basiliximab, a chimeric monoclonal antibody (25% murine) is the only available IL-2 receptor antagonist in the United States. Daclizumab, a humanized monoclonal antibody (90% human, 10% murine) was withdrawn in 2009. Daclizumab contains a greater proportion of human sequences, making it theoretically less
immunogenic. The percentage of murine component determines the antibody’s affinity for the epitope. Consequently, the chimeric antibody basiliximab has a higher affinity than daclizumab.63

**Pharmacology/Mechanism of Action** Both basiliximab and daclizumab exert their immunosuppressive effect by specifically binding to the α-chain (CD25) on the surface of activated T lymphocytes (see Fig. 98–1). Binding of either basiliximab or daclizumab to the IL-2 receptor prevents IL-2-mediated activation and proliferation of T cells, a critical step in clonal expansion of T cells and the development of allograft rejection. Saturation of the IL-2 receptor occurs rapidly and confers an immunosuppressive effect immediately.65

**Pharmacokinetics** Most of the pharmacokinetic data available for both basiliximab and daclizumab are in renal transplantation patients. Caution must be used when extrapolating these data to nonrenal transplantation recipients. The volume of distribution is approximately 5.3 L for daclizumab and 8 L for basiliximab. Basiliximab and daclizumab saturate CD25 in vivo at serum concentrations of 0.2 and 1 mg/L or greater, respectively.64 The terminal half-life of daclizumab is about 20 days in renal transplantation patients compared with 3 to 4 days in bone marrow transplant recipients. Basiliximab has a shorter half-life of approximately 7 days in renal transplant recipients. Clearance of both drugs is increased in patients who have received a liver transplant, primarily as a consequence of drainage of ascites. It is recommended that patients with greater than 10 L of ascites receive an additional dose of basiliximab on postoperative day 8.65 Therapeutic concentrations of daclizumab range from 5 to 10 mg/L.

**Efficacy** Both basiliximab and daclizumab are approved for use in kidney transplantation in combination with cyclosporine and corticosteroids, although induction therapy has also been studied extensively in liver and heart transplantation recipients. In 2006 28% of kidney and heart transplant recipients received an IL-2 receptor antagonist at the time of transplant.1 A meta-analysis of daclizumab and basiliximab in renal transplantation concluded that IL-2 receptor antagonists reduced the risk of rejection significantly with no increases in graft loss, infectious complications, malignancy, or death.66 Similar results were seen in liver and heart transplantation.67

IL-2 receptor antagonists offer a reasonable addition to calcineurin inhibitor– or corticosteroid-sparing protocols. While calcineurin inhibitor therapy can not be completely avoided in most cases,64 IL-2 receptor antagonists allow for delayed use or reduced doses of calcineurin inhibitors, thus minimizing the risk of nephrotoxicity in the early post-transplantation period. Similar rates of rejection and corticosteroid-resistant rejection were seen in patients with DGF who received an IL-2 receptor antagonist in conjunction with lower tacrolimus doses compared with patients without DGF who received standard tacrolimus doses and no IL-2 receptor inhibitor induction.65

**Adverse Effects** Few adverse effects have been reported with basiliximab and daclizumab. In contrast to lymphocyte-depleting agents, basiliximab and daclizumab have not been associated with infusion-related reactions. However, since the marketing of basiliximab, an increased number of hypersensitivity reactions have been reported. Of note, only one patient developed anti-idiotypic antibodies to the murine portion during clinical trials.69 The manufacturer of basiliximab reported an increase in mortality in a placebo-controlled trial, which was associated with an increase in severe infections. No increased risk of malignancy has been reported.

**Drug–Drug and Drug–Food Interactions** Reports of increased cyclosporine and tacrolimus levels in patients receiving concomitant basiliximab were recently published.63,64 Both authors hypothesized a potential interaction with the cytochrome P450. No drug interactions have been reported with daclizumab.

**Dosing and Administration** Basiliximab is administered as two 20-mg intravenous doses, intraoperatively and again on postoperative day 4. Basiliximab is compatible with both 0.9% sodium chloride and 5% dextrose and can be administered either centrally or peripherally over 20 to 30 minutes in a volume of 50 mL. This regimen results in saturation of the IL-2 receptor for 30 to 45 days. The approved daclizumab dosing regimen for renal transplantation is 1 mg/kg every 2 weeks from the time of transplant for a total of 5 doses. Daclizumab should be diluted in 50 mL of sterile 0.9% sodium chloride and administered peripherally or centrally over 15 minutes. This regimen saturates the IL-2 receptors for approximately 90 to 120 days after renal transplantation.64 Alternative dosing regimens have been proposed for daclizumab in combination with tacrolimus, mycophenolate, and corticosteroids: 1 mg/kg every 2 weeks for 5 doses, 2 mg/kg every 2 weeks for 2 doses, or 2 mg/kg on day 0 followed by 1 mg/kg on day 5.64,65

**Investigational Agents**

**Belatacept** Belatacept, derived from abatacept, is a selective costimulation blocker that binds costimulatory ligands (CD80 and CD86) on antigen presenting cells. This prevents interaction of CD80 and 86 with CD28 on T cells thus inhibiting T-cell activation. Belatacept is still in the investigational phase of development.68 In a phase II evaluation of two dosing strategies of belatacept versus cyclosporine in combination with basiliximab, mycophenolate mofetil, and corticosteroids in 218 renal transplant patients there was no difference in the rates of acute cellular rejection at 6 months. However, in patients treated with belatacept, GFR as measured by iohexol clearance was significantly higher than cyclosporine-treated patients at 12 months. Chronic allograft nephropathy as detected by protocol biopsy was also significantly lower in the belatacept groups. Belatacept has been well tolerated. At 12-month follow-up no adverse effects were reported in greater number in the belatacept groups. Cyclosporine–treated patients experienced more hypertension and hyperlipidemia.68

Belatacept was administered by intermittent intravenous infusion. While this improves compliance in some patients, the inability to reverse immunosuppression in patients with life-threatening infections may hinder acceptance.69 Ongoing trials will define dosing strategies and place in transplant therapy, if any, for belatacept.

**Bortezomib** Bortezomib, a proteasomal inhibitor that is FDA approved for the treatment of multiple myeloma, has recently been used in the treatment of AMR. Everly and colleagues reported the use of bortezomib in six renal transplant recipients with AMR and concurrent ACR. In this small series rejection was reversed, donor-specific antibody levels decreased, and renal allograft function improved. All patients received four doses of intravenous bortezomib 1.3mg/m². Side effects included gastrointestinal, thrombocytopenia, and paresthesias.68 Bortezomib may also be effective in preventing the development of AMR. Trivedi and colleagues used four doses of bortezomib 1.3 mg/m² in a group of patients with elevated anti-HLA antibody levels in the absence of acute rejection after transplantation. Patients also received methylprednisolone and treatment with plasmapheresis. Antibody elevations resolved in 9 of 11 patients in 14 to 87 days. The incidence of rejection was not reported.70

**Rituximab** Rituximab is a humanized monoclonal antibody against the CD20 receptor found on B cells. While it is FDA approved for non-Hodgkin lymphoma and rheumatoid arthritis, it has also been used in various aspects of transplant medicine, including treatment of AMR and suppression of alloantibodies prior to transplantation.71 The optimal dose of rituximab in transplantation has not been defined.
The success of transplantation can be measured in terms of length of graft and patient survival or quality of life. Several donor and recipient factors that have an impact on graft and patient survival have been identified (Table 98–8). The greatest risk to short-term graft survival is acute rejection. Routine surveillance of appropriate biochemical markers and serum drug concentrations are essential to minimize the potential for acute rejection. These parameters should be assessed daily to weekly for the first 1 to 3 months after transplantation. Monitoring should include complete blood counts, serum electrolyte concentrations, serum creatinine and blood urea nitrogen concentrations, and the appropriate serum drug concentrations. Liver function tests should also be evaluated using the same schedule in liver transplantation recipients. Routine biopsies are necessary to monitor for acute rejection in heart transplantation recipients. As the time after transplantation increases, the frequency of monitoring decreases. Once 3 months have elapsed after transplantation, monitoring of these parameters can be reduced to biweekly or monthly for most patients.

Long-term graft survival is limited by chronic rejection. Overall survival rates for solid-organ transplants are described in terms of half-life, or the time after transplantation at which only 50% of transplanted organs are still functioning. Estimated half-lives for kidneys are 26.9 years for HLA-identical grafts and 12.2 and 10.8 years, respectively, for grafts from a sibling or parent who are 1-haplotype matches. The estimated half-life for HLA-matched grafts was 17.3 years while a markedly lower value of 7.8 years has been noted with mismatched kidneys. The overall median patient survival time for heart transplantation recipients is 9.8 years, but in these patients surviving the first year after transplantation, the median survival increases to 12 years. The highest rate of mortality occurs within the first year after liver transplantation due to the risks of surgery and early postoperative complications. Table 98–9 depicts a typical post-transplantation laboratory monitoring plan.

### ECONOMIC CONSIDERATIONS

Renal transplant has been shown to be the most cost-effective means of chronic renal replacement therapy. The degree to which patients remain eligible for Medicare coverage after transplantation impacts kidney allograft survival, presumably secondary to effects on medication availability and compliance. Lifetime extension of Medicare-covered immunosuppression has been associated with improved allograft survival in low-income recipients, with a relative reduction in graft failure rates of 21–27%. In patients who do not otherwise qualify due to age or disability, Medicare currently only provides coverage for immunosuppression for the first 3 years after transplant. Noncompliance has been associated with a sevenfold increased risk of graft failure.

The assessment of the economic impact of liver and heart transplantation is complex. Unlike renal transplantation, liver and heart transplantation is lifesaving. However, there are factors that impact the overall cost of liver transplant that may impact patient selection. Patients awaiting transplant at home, for example, cost less than those who were hospitalized ($114,000 vs $154,000 and $211,000 for ward and ICU care, respectively). Malnutrition and renal impairment have also been shown to increase costs associated with liver transplant by 38% and 39%, respectively. It has been estimated that the total charges for a given heart transplant were approximately $300,000 for the first year, with an additional $20,000 per year of follow-up. If cardiac-assist devices become a viable long-term therapeutic option for end-stage heart failure, the treatment will have a significant therapeutic as well as economic impact.

BUN, blood urea nitrogen; HbA1c, hemoglobin A1c; SCr infusion, serum creatinine.

*aChemistry includes sodium, potassium, chloride, CO2 content, magnesium, calcium, phosphorus, and blood glucose.

*bLiver function tests include total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), gamma-glutamyl transpeptidase (GGTP), alkaline phosphatase.

*cComplete blood count includes white blood cells (WBC), red blood cells (RBC), platelets, and/or differential.

*dLipid panel includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglyceride, and/or very low-density lipoprotein (VLDL).
Corticosteroids, cyclosporine, tacrolimus, and impaired kidney graft function may cause post-transplantation hypertension. The primary mechanism of calcineurin inhibitor–associated hypertension in heart transplantation recipients may be related to the calcineurin inhibitor–induced stimulation of intact renal sympathetic nerves and the absence of reflex cardiac inhibition of the sympathetic nervous system, but a number of other mechanisms, including decreased prostacyclin and nitric oxide production have also been proposed.\textsuperscript{80,83,84} In addition to the propensity to cause peripheral vasoconstriction, calcineurin inhibitors promote sodium retention, resulting in extracellular fluid volume expansion. Tacrolimus appears to have less potential to induce hypertension following transplantation than cyclosporine.\textsuperscript{24,85}

Calcium channel blockers have traditionally been the first-line agents to treat hypertension after transplantation.\textsuperscript{46} Calcium channel blockers may ameliorate the nephrotoxic effects of cyclosporine, improve renal hemodynamics, decrease the incidence of DGF and the development of allograft atherosclerosis, and provide some immunosuppression. Calcium channel blockers, however, may also contribute to gingival hyperplasia that is often associated with cyclosporine-based immunosuppression.\textsuperscript{81}

ACEIs and angiotensin II receptor blockers have traditionally been avoided in kidney transplantation recipients, especially in the perioperative phase, because of the potential for hyperkalemia and their potentially negative influence on glomerular filtration rate. ACEIs and angiotensin II receptor blockers are now considered to be an equivalent alternative to calcium channel blockers for the treatment of hypertension in all transplant recipients. When ACEIs or angiotensin II receptor blockers are used in patients after transplantation, serum creatinine and potassium levels should be monitored closely. If the increase in serum creatinine is greater than 30% within 1 to 2 weeks after initiating ACEIs or angiotensin II receptor blockers, other alternatives must be considered (see Chap. 19).

Multiple antihypertensive agents are usually necessary to achieve the goal blood pressure in transplant recipients; consequently, the addition of a \textit{β}-blocker, diuretic, or centrally acting antihypertensive is usually necessary. Beta-Blockers are generally considered to be second-line therapy in solid-organ transplantation recipients because of the potential to worsen metabolic disturbances caused by immunosuppressants, such as hyperkalemia and dyslipidemia. Calcineurin inhibitor–induced hypertension is often salt-sensitive, making it very responsive to diuretics. Central-acting agents (e.g., clonidine) are used often as adjunctive therapy in transplantation recipients who are unable to achieve blood pressure control with calcium channel blockers or ACEIs.

**HYPERTENSION**

**IMMUNOSUPPRESSION-RELATED COMPLICATIONS**

Comorbidities such as cardiovascular disease and malignancy, recurrent disease, drug toxicities (namely nephrotoxicity), and chronic rejection are the primary causes of mortality in patients who have a functioning graft 5 or more years after transplantation.\textsuperscript{1}

**CARDIOVASCULAR DISEASE**

Cardiovascular disease is a leading cause of morbidity and mortality in transplant patients.\textsuperscript{40} Preexisting cardiovascular disease, which is common in end-stage organ failure, is not reversed with transplantation. Additionally, hypertension, hyperlipidemia, and diabetes are common complications in transplantation recipients and are independent risk factors that contribute significantly to cardiovascular disease. Chronic rejection has been linked to hypertension and hyperlipidemia.\textsuperscript{81,82}
For most patients, the combination of dietary intervention and an HMG-CoA reductase inhibitor should be considered the treatment of choice. HMG-CoA reductase inhibitors are highly effective in the treatment of hyperlipidemia, especially increased LDL, in transplantation patients. HMG-CoA reductase inhibitors as a class also have immunomodulatory effects on MHC expression and T-cell activation and reduce cardiac allograft rejection.22,89

HMG-CoA reductase inhibitors should be used with caution in transplantation recipients because of several reports of rhabdomyolysis when these agents are combined with calcineurin inhibitors.35,89 Safety measures include using low HMG-CoA reductase inhibitor doses and avoiding inappropriately high cyclosporine or tacrolimus concentrations. The concurrent use of medications known to increase the risk of myopathy (such as gemfibrozil) should be avoided.82 Patients should be informed of the signs and symptoms of rhabdomyolysis. Baseline and follow-up creatine phosphokinase measurements (every 6 months) have been used to identify patients who develop subclinical rhabdomyolysis when cholesterol-lowering therapy is used. Pravastatin may be preferred as a result of its lower interactive potential with calcineurin inhibitors because it is not metabolized by CYP3A4. The potential for hepatotoxicity from HMG-CoA reductase inhibitors warrants close monitoring of liver function in all transplantation recipients.87

Bile acid–binding resins may be used to lower cholesterol in transplant patients, but adequate doses are difficult to achieve without the development of GI adverse effects. Because the absorption of cyclosporine is dependent on the presence of bile in the GI tract, patients should be instructed to separate dosing of bile acid–binding resins and cyclosporine by at least 2 hours. Bile acid–binding resins should also be separated from other immunosuppressants by at least 2 hours to avoid physical adsorption in the GI tract. For transplant patients who have hypertriglyceridemia refractory to dietary intervention, fish oil and fibric acid derivatives are well-tolerated, effective alternatives (see Chap. 28). Fibric acid derivatives are most effective in lowering serum triglyceride concentrations.

New-Onset Diabetes after Transplantation

Corticosteroids and calcineurin inhibitors can impair glucose control in previously diabetic patients, as well as cause new-onset diabetes after transplantation (NODAT) in 4% to 20% of patients. Corticosteroids induce insulin resistance and impair peripheral glucose uptake, whereas calcineurin inhibitors appear to inhibit insulin production.55 Tacrolimus seems to be more diabetogenic than cyclosporine, although recent studies have failed to show a statistical difference.22 Other possible risk factors that have been identified for NODAT include African American or Hispanic ethnicity, age >40 years, family history, and weight, as well as CMV and Hepatitis C virus infection.54

Up to 40% of patients with NODAT will require insulin therapy.43 In diabetic patients who can be managed with an oral hypoglycemic agent, glipizide, which is metabolized extensively by the liver, may be preferred over renally eliminated agents such as glyburide. Metformin should be used with extreme caution because of the risk of accumulation and lactic acidosis in those with moderate renal impairment. Regardless of therapy, frequent blood glucose monitoring is imperative in the early postoperative phase both to improve glucose control and to identify those with NODAT. Changes in renal function secondary to calcineurin inhibitor nephrotoxicity or DGF or acute rejection in kidney transplant recipients affects the elimination of many hypoglycemic agents, including insulin, and may result in hyper- or hypoglycemia. Dose changes of immunosuppressive drugs also affect glycemic control. Tapering of immunosuppressive medications may result in reduced insulin requirements, whereas corticosteroid pulses for the treatment of rejection may result in increased insulin requirements.

INFECTION

Increased risk of infection is a natural consequence of therapeutic immunosuppression. Many infections, including cytomegalovirus and fungal infections, in solid organ transplant recipients are reviewed in Chapter 131.90

Polyomavirus-associated nephropathy (PVAN) is an important cause of renal dysfunction in kidney transplant recipients. The specific polyomavirus that infects kidney allografts is the BK virus. Primary infection with BK virus occurs in childhood as an asymptomatic infection in 50% to 90% of the general population. The precise mechanism of transmission is not clear but is suspected to be via the oral or respiratory routes. The virus then remains latent primarily in the genitourinary tract. Reactivation of BK virus is limited to people with compromised immune function and is most common in kidney transplant recipients. Reactivation can be detected as the presence of BK virus in the urine of approximately 30% to 40% of kidney transplant recipients, although it does not progress to nephropathy in the majority of patients. However, BK viremia if it develops has been noted to progress to allograft nephropathy in 50% of patients.91 The development of BK virus nephropathy results in graft loss in about 46% of affected patients.91

It has been recommended that all kidney transplant recipients be screened for urinary BK virus replication at least every 3 months during the first 2 years post-transplant or in the event of any renal dysfunction or allograft biopsy. If positive, the result should be confirmed within 4 weeks by quantitative assay in plasma or urine. PVAN is definitively diagnosed by kidney allograft biopsy but may be mistaken for acute rejection if the pathologist does not recognize the presence of BK virus inclusions in renal tubular cells. Differentiation between the two is very important as treatment of acute rejection with increased immunosuppression can worsen BK virus nephropathy. The mainstay of treatment is a reduction in immunosuppression, which should be instituted when BK viremia is detected. The risks of acute rejection resulting from decreased immunosuppression must be weighed against the potential benefits of resolving BK viremia. Cidofovir, a potent nephrotoxic antiviral used for the treatment of CMV retinitis, has also been used for the treatment of BK virus in very low doses (0.25–0.33 mg/kg) without probenecid administered every 2 to 3 weeks.92

Hepatitis C recurs almost universally following liver transplantation, resulting in chronic hepatitis or cirrhosis in 90% of patients by 5 years. These patients tend to experience a much more aggressive course than that observed in immunocompetent patients. While short-term survival is not affected, hepatitis C virus infection recurrence results in the need for retransplantation in more than 10% of patients originally transplanted for hepatitis C virus. Pegylated interferons as monotherapy or in combination with ribavirin have been used after liver transplantation, in both the acute and chronic phases of hepatitis C virus infection and as prophylactic or preemptive therapy. Although some patients do achieve sustained viral responses, the rates are generally lower than for immunocompetent patients, 10% to 30% versus 30% to 70%, respectively, for combination therapy. Preexisting anemia and renal dysfunction make it difficult to maintain ribavirin at effective doses. Combination of immunosuppressive drugs and interferon may result in dose-limiting neutropenia. Administration of hematopoietic growth factors may be needed to allow administration of adequate doses of interferons and ribavirin. Even with these adjunctive therapies high rates of therapy discontinuation are still reported.93,94

In the absence of preventative therapy, hepatitis B recurs in approximately 80% of patients. Initial studies with short-term
in intravenous administration of hepatitis B immunoglobulin (HBlg) showed equally high rates of recurrence upon discontinuation of therapy. However, strategies that employ the long-term administration of HBlg with or without antiviral therapy report much lower recurrence rates, 15% to 30% and 20% to 40%, for nonreplicative and replicative hepatitis B virus, respectively. Common strategies include intravenous HBlg 10,000 units during the anhepatic phase followed by 10,000 units daily for 6 days. Antihepatitis B surface titer should be monitored weekly to ensure adequate levels for protection as well as to optimize HBlg use. HBlg has been typically dosed to maintain titers >100 to 500 international units/L. Long-term HBlg therapy is extremely costly, estimated at $100,000 for the first postoperative year and $50,000 for each subsequent year. Combination therapy with antiviral agents appears to be synergistic and is the current standard. Lamivudine resistance is a concern with long-term utilization both pre- and post-transplant. The role of newer antiviral agents, including adefovir, entecavir, and tenofovir, remains to be defined. Other strategies that have been investigated and show promise include pretransplant viral load reduction and reduced-dose HBlg. Treatment for active hepatitis B virus graft infection should include HBlg, antiviral therapy, and concomitant reduction in immunosuppression.94

**MALIGNANCY**

Although advances in immunosuppression have decreased the incidence of acute rejection and increased patient survival, they have also increased the patient’s lifetime exposure to immunosuppression. While the precise mechanism is unclear, post-transplantation malignancy seems to be related to the overall level of immunosuppression, as evidenced by a difference in the rates of malignancy associated with quadruple versus triple versus dual immunosuppressant regimens. The risk of de novo malignancy in transplantation recipients is increased three- to fivefold over the general population. The age-adjusted incidence of lung, breast, colon, and prostate cancers was doubled in renal transplant recipients. A number of cancers that are uncommon in the general population occur with much higher prevalence in transplantation recipients: post-transplantation lymphomas and lymphoproliferative disorders (PTLDs), Kaposi sarcoma, renal carcinoma, in situ carcinomas of the uterine cervix, hepatobiliary tumors, and anogenital carcinomas. Skin cancers are the most common tumors. Factors that may predispose transplant recipients to skin cancers include copious sun exposure and therapy with azathioprine.95 While too early to definitively assess the impact of mycophenolic acid derivatives on malignancy, one analysis showed a lower risk of PTLD with MMF compared with AZA. Inhibitors of mTOR have a theoretical benefit in terms of the development of malignancy. In addition to immunosuppressive properties, mTOR inhibitors also have antiproliferative effects. In fact, a decreased incidence of malignancy was reported in patients receiving mTOR inhibitors versus CNIs, and conversion to PSIs from CNIs can result in regression of Kaposi sarcoma.96

PTLD encompasses a broad spectrum of disorders, ranging from benign polyclonal hyperplasias to malignant monoclonal lymphomas. Factors that predispose patients to PTLD include Epstein-Barr virus seronegativity at transplantation and intense immunosuppression, particularly with OKT3 and antithymocyte globulin. Nonrenal transplantation recipients are more likely to develop PTLD secondary to the heavy immunosuppression used to reverse rejection. Administration of ganciclovir or acyclovir preemptively during antilymphocyte therapy may decrease the risk of eventual PTLD. Treatment of life-threatening PTLD generally includes severe reduction or cessation of immunosuppression. Other options include systemic chemotherapy or rituximab.96 Post-transplantation malignancies appear an average of 5 years after transplantation and increase with the length of follow-up. As many as 72% of patients surviving greater than 20 years may be affected. Malignancy accounts for 11.8% of deaths after cardiac transplantation and is the single most common cause of death in the sixth to the tenth post-transplant years.95

**CONCLUSIONS**

Transplantation is a lifesaving therapy for several types of end-organ failure. Advances in the understanding of transplant immunology have produced an unprecedented number of choices in terms of immunosuppression. The increasing number of effective immunosuppressive medications and therapies offers clinicians diverse ways to prevent allograft rejection in a patient-specific manner. However, the vast array and efficacy of currently available immunosuppressive agents make it increasingly difficult to evaluate their long-term efficacy. Clinicians must be keenly aware of the adverse effects of immunosuppressive medications and their treatment in order to optimize the care of the transplanted patient.

**ABBREVIATIONS**

6-MP: 6-mercaptopurine
ACEI: angiotensin-converting enzyme inhibitor
ACR: acute cellular rejection
AMR: antibody-mediated rejection
ATG: antithymocyte globulin
ATN: acute tubular necrosis
AUC: area under the concentration curve
Cmax: peak concentration
CMV: cytomegalovirus
CYP: cytochrome P450 liver enzyme system
DGF: delayed graft function
FKBP: FK-binding protein
GI: gastrointestinal
HBIg: hepatitis B immunoglobulin
HIV: human immunodeficiency virus
HLA: human leukocyte antigen
HPLC: high-performance liquid chromatography
IL: interleukin
LDL: low-density lipoprotein
MELD: model for end-stage liver disease
MHC: major histocompatibility complex
MPA: mycophenolic acid
MPAG: mycophenolic acid glucuronide
mTOR: mammalian target of rapamycin
NODAT: new-onset diabetes after transplantation
OKT3: muromonab-CD3
PML: progressive multifocal leukoencephalopathy
PRA: panel of reactive antibodies
PSI: proliferation signal inhibitor
REFERENCES

SECTION 11
Immunologic Disorders

Osteoporosis and Other Metabolic Bone Diseases

KEY CONCEPTS

1. Perimenopausal and postmenopausal women, men older than age 50 years, and those with potential disease- or medication-induced bone loss should be assessed for osteoporosis. Patients with early-onset or severe osteoporosis should be evaluated for secondary causes of bone loss.

2. Inadequate vitamin D concentrations, which sometimes cause osteomalacia, can be insidious and coexist with osteoporosis. A serum 25(OH) vitamin D concentration should be obtained in patients with osteoporosis, at high risk for low vitamin D concentrations, or with symptoms suggestive of inadequate vitamin D such as unexplained muscle weakness, falls, or pain.

3. Osteoporosis in men is often secondary to certain diseases and medications and responds well to a bone-healthy lifestyle, bisphosphonate or teriparatide therapy, and in some cases, testosterone replacement.

4. Estimation of an adult person’s 10-year probability of developing an osteoporotic fracture can be estimated with the FRAX tool. Central bone densitometry can determine bone mass, predict fracture risk, and influence patient and provider treatment decisions. Portable equipment can be used for screening in the community to determine the need for further testing.

5. All people, regardless of age, should incorporate a bone-healthy lifestyle beginning at birth and continuing throughout life, that emphasizes regular exercise, nutritious diet, tobacco avoidance, minimal alcohol use, and fall prevention to prevent and treat osteoporosis.

6. The adequate intake for calcium in American adults is 1,000 to 1,200 mg of elemental calcium daily in divided doses from diet or supplements. The adequate intake for American adults is 400 to 1,000 units (seniors 800–1,000 units) of vitamin D daily, mainly from supplements, with some experts recommending higher doses.

7. Bisphosphonates decrease vertebral, hip, and nonvertebral fractures and are considered the medication of choice for osteoporosis treatment. Adherence with bisphosphonates is frequently suboptimal, which has been associated with less fracture prevention. Assessment of correct administration should be frequently conducted with repeat patient education as needed.

8.Raloxifene is an alternative treatment option to prevent vertebral fractures, particularly in women who cannot tolerate, should not, or will not take bisphosphonates. Raloxifene also decreases invasive breast cancer risk. Postmenopausal women at high risk for breast cancer might choose this medication to obtain dual benefits.

9. Healthcare providers can have an important role in prevention and treatment of osteoporosis by conducting osteoporosis assessments at health fairs and community pharmacies, identifying and resolving disease and medication-induced bone loss/osteoporosis, ensuring medications are taken accurately, identifying and resolving medication-related problems resulting in suboptimal adherence, and encouraging secondary fracture prevention in patients with past hip or vertebral fractures.

10. Patients taking long-term oral glucocorticoids need to be identified and started on a bone-healthy lifestyle with higher intakes of calcium and vitamin D and usually bisphosphonate therapy to prevent or treat osteoporosis.

11. Osteoporosis is a major public health threat for an estimated 44 million Americans or 55% of the people 50 years of age and older. Low bone density (sometimes referred to as osteopenia) is estimated in 34 million Americans and in 37% to 50% of white women. In the United States, 8 million women and 2 million men are estimated to have osteoporosis. Osteoporosis is a bone disorder characterized by low bone density, impaired bone architecture, and compromised bone strength predisposing a person to increased fracture risk. The development of osteoporosis and osteoporotic fractures is...
multifactorial, beginning with genetics and lifestyles unhealthy for bone growth and maintenance, along with other skeletal factors, which lead to compromised bone strength, and nonskeletal factors that lead to falls (Fig. 99–1). Everyone must take an active role in educating people of all ages as well as other healthcare providers on healthy bone lifestyle habits and osteoporosis prevention and treatment options.

**EPIDEMIOLOGY**

Osteopenia, osteoporosis, and osteoporotic fractures are very common and affect all ethnic groups. Osteopenia is estimated to occur in 50% of Asian, 47% of Hispanic, 45% of Native American, 40% of white, and 28% of black women. Osteoporosis affects 12% of Native American, 10% of Asian, 10% of Hispanic, 7% of white, and 4% of black women. Disease prevalence greatly increases with age; from 4% in women 50 to 59 years of age to 44% to 52% in women 80 years of age and older. White and Hispanic women have the highest fragility fracture rate followed by Native American, African American, and Asian women when the data are adjusted for weight, bone mineral density (BMD), and other factors. About 8 to 13 million men aged 50 years and older (i.e., 28%–47%) have osteopenia, with an osteoporosis prevalence of 6% to 13%. Although osteoporosis is a common finding in seniors with fractures, up to 50% of fragility fractures occur in patients with normal bone mass or osteopenia.

Low trauma (fragility) wrist and vertebral fractures are common throughout adulthood, and hip fractures are more common in seniors. Fracture incidence was estimated to be 2 million (71% in women, 29% in men) in 2005, with an estimated total medical cost of $17 billion. Fractures in women accounted for 75% of the costs and in seniors 87% of the costs. Hip fractures represented 72% of these costs. Forecasting predicts 3 million fractures at a cost of $25 billion in 2025. Newer information is beginning to suggest that fracture incidence might be decreasing for both sexes, with the hypothesis related to better efforts at osteoporosis prevention (e.g., improved risk factor identification, diagnosis, and bone-healthy lifestyle education) and use of prescription antosteoporotic medications. In a woman’s lifetime, she has a 17% likelihood of a hip fracture, 15.6% likelihood of a vertebral fracture, and 16% likelihood of a forearm fracture. In a man’s lifetime, osteoporotic fracture risk is 15%.

**BONE PHYSIOLOGY**

The skeleton comprises two types of bone. Cortical bone makes up the majority of the skeleton (80%) and is found mostly in the long bones (e.g., forearm and hip). Trabecular bone is found mostly in the vertebrae and ends of long bones. It is 10 times more metabolically active compared with cortical bone, having a much higher bone turnover rate because of its large surface area and honeycomb-like shape.

Bone is made of collagen and mineral components. The collagen component gives bone its flexibility and energy-absorbing capability. The mineral component gives bone its stiffness and strength. The correct balance of these substances is needed for bone to adequately accommodate stress and strain and resist fractures. Imbalances can impair bone quality and lead to reduced bone strength.

Bone strength reflects the integration of bone quality and BMD (bone mass). Bone mass increases rapidly throughout childhood and adolescence. Ninety-five percent of peak bone mass is attained by age 18 to 20 years, with small gains until approximately age 30 years. Peak bone mass is highly dependent on genetic factors that account for approximately 60% to 80% of the variability. The remaining 20% to 40% is influenced by modifiable factors such as nutritional intake (e.g., calcium, vitamin D, and protein), exercise,
adverse lifestyle practices (e.g., smoking), hormonal status, and certain diseases and medications. Optimizing peak bone mass is important for preventing osteoporosis. The higher the peak bone mass, the more bone one can lose before being at an increased fracture risk.

Bone remodeling is a dynamic process that occurs continuously throughout life Figure 99–2.9,12–16 One to two million tiny sections of bone are in the process of remodeling at any given time. The complete physiology of bone remodeling is not fully known but appears to begin with signals from lining cells or osteocytes (bone communication cells) that are triggered by stress, microfractures, biofeedback systems, and potentially certain diseases and medications (see Fig. 99–2, step 1).17 Many cytokines, growth factors, and hormones influence each remodeling step. A major stimulus for hematopoietic stem cell (monocyte–macrophage lineage) differentiation to become mature osteoclasts (bone resorbing cells) is the receptor activator of nuclear factor kappa B ligand (RANKL), which is emitted from the osteoblast (bone-forming cells) in step 2 and binds to its receptor RANK on the surface of osteoclast precursors. RANKL also stimulates mature osteoclast activation and bone adherence via integrins to resorb bone. Proteinases are secreted to resorb the protein matrix, and hydrogen ions are secreted to dissolve the mineralized component (step 3). After bone is resorbed and a cavity is created, additional cytokines and growth factors, some working through Wnt/β-catenin pathways, are released that first mature osteoblasts from mesenchymal stem cells and then stimulate bone formation (step 4). Osteoclasts also produce ephrinB2 that adheres to ephB4 receptors on osteoblasts and osteoblast precursors to stimulate osteoblast differentiation and activity. Mature osteoblasts produce osteoprotegerin (OPG) that binds (step 4) to RANKL, thereby stopping bone resorption.

Bone formation occurs over two phases.9,13,16 First, osteoblasts fill the resorption cavity with osteoid, and then mineralization occurs (step 5). Once bone formation is complete, mature osteoblasts undergo apoptosis or become lining cells or osteocytes (step 6). Osteocytes produce sclerostin, which inhibits Wnt signaling and bone formation. Quiescence is the phase when bone is at rest until another remodeling cycle is initiated at that site.

With the mapping of the genome, exploration into genetic control of bone physiology and pathophysiology is being explored.18 Nine genes have been mapped to BMD regulation and four genes to fracture risk. Genetic modulation is in its infancy for osteoporosis prevention and treatment but might lead to new medications.

Estrogen has many positive effects on the bone remodeling process, with most of its actions helping to maintain a normal bone resorption rate.12,19 Estrogen suppresses the proliferation and differentiation of osteoclasts and increases osteoclast apoptosis. Estrogen decreases the production of several cytokines that are
potent stimulators of osteoclasts, including interleukins 1 and 6, and tumor necrosis factor-α. Estrogen also decreases the production of RANKL and increases the production of OPG, both of which reduce osteoclastogenesis.20

**VITAMIN D, PARATHYROID HORMONE, AND CALCIUM**

Vitamin D and parathyroid hormone (PTH) work together to maintain calcium homeostasis. The most abundant source of vitamin D is the endogenous production from exposure to ultraviolet B light. The sun’s ultraviolet B light converts 7-dehydrocholesterol in the skin to cholecalciferol (vitamin D$_3$).21,22 Dietary vitamin D sources include cholecalciferol and ergocalciferol (vitamin D$_2$). Subsequent conversion of cholecalciferol and ergocalciferol to 25-hydroxyvitamin D [25(OH) D] (calcidiol) occurs in the liver, and then PTH stimulates conversion of 25(OH) vitamin D via 25(OH) vitamin D-1α-hydroxylase to its final active form, 1α,25-dihydroxyvitamin D (calcitriol), in the kidney. Calcitriol binds to the intestinal vitamin D receptor and then increases calcium-binding protein. As a result, calcium and phosphorous intestinal absorption is increased.

Vitamin D receptors are also found in many tissues, such as bone, intestine, brain, breast, colon, heart, stomach, pancreas, lymphocytes, skin, and gonads.23 Some cells within these tissues contain 1α-hydroxylase and have the capacity to convert vitamin D to its active form.21 Vitamin D is increasingly recognized as contributing many nonbone benefits, and those may relate to the presence of these conversion capabilities and receptors throughout the body.

1. Inadequate concentrations of vitamin D are common in all age groups, especially in seniors and individuals who are malnourished or obese, live in an institution (e.g., nursing home), or live in more northern latitudes.22 Low vitamin D concentrations result from insufficient intake, dietary fat malabsorption, decreased sun exposure, decreased skin production, or decreased liver and renal metabolism. Endogenous synthesis of vitamin D can be decreased by factors that affect exposure to or decrease skin penetration of ultraviolet B light. Sunscreen use, full body coverage with clothing (e.g., women wearing veiled, full-length dresses), and darkly pigmented skin can all cause a decrease in vitamin D production. Seasonal variations in vitamin D concentrations are also seen with nadirs in late winter and peaks in late summer.23

2. Calcium absorption under normal conditions is approximately 30% to 40%, decreasing to 10% to 15% with low vitamin D concentrations.23,24 Calcium absorption is predominantly an active rate-limited process controlled by many hormones such as vitamin D and estrogen. Less than 15% is absorbed through passive diffusion, which is not rate limited.23,25 A calcium transporter is required to bring calcium from the gut into the tissue wall. Then it binds to calbindin to be transported across the enterocyte and is extruded into the circulation via Ca$^{2+}$ adenosinetriphosphatase (ATPase) and the sodium/calcium exchanger (NCX). When the calcium sensing receptor (CaSR) on parathyroid cells senses low serum calcium, PTH production increases. PTH then increases calcitriol production and calcium reabsorption by the kidney. Calcium absorption increases as 25(OH) vitamin D concentrations increase until 29 to 32 ng/mL (72–80 nmol/L) when the effect plateaus; this observation provides the rationale for the cutoff point for vitamin D sufficiency at around 30 ng/mL (75 nmol/L).22,27 Sometimes the increased fractional calcium absorption is insufficient to maintain normal serum calcium, and thus bone resorption is needed for correction. Together, PTH and calcitriol increase osteoclast activity, thereby releasing calcium from bone to restore calcium homeostasis.

Low physical activity
Minimal sun exposure
Poor health/frailty
Recent falls
Cognitive impairment
Impaired vision |

*Factors included in the World Health Organization fracture risk assessment tool (FRAX).
Secondary causes included in the FRAX tool question are diabetes type 1, osteogenesis imperfecta as an adult, long-standing untreated hyperthyroidism, hypogonadism, premature menopause (before 45 years of age), chronic malnutrition, malabsorption, and chronic liver disease.

**ETIOLOGY**

1. Figure 99–1 depicts a model describing the etiology of osteoporosis and fractures. Table 99–1 lists risk factors for osteoporosis, and Tables 99–2 and 99–3 list secondary causes of this condition.

**LOW BONE DENSITY**

BMD is a major predictor of fracture risk. Every standard deviation decrease in BMD in women represents a 10% to 12% decrease in bone mass and a 1.5- to 2.6-fold increase in fracture risk.2 Low BMD can occur as a result of bone loss or failure to reach a normal peak bone mass.

Bone loss occurs when bone resorption exceeds bone formation, usually from high bone turnover; when the number or depth of bone resorption sites greatly exceeds the rate and ability of osteoblasts to form new bone. Women and men begin to lose a small amount of bone mass starting in the third to fourth decade of life as a consequence of a slight reduction in bone formation.3 During perimenopause and for up to 4 years after menopause, women can experience an accelerated rate of bone loss because of the drop in circulating estrogen and subsequent increase in bone resorption.2,20 The rate and duration of loss can vary greatly, with up to 2% to 5% of bone density lost per year, and can differ depending on the skeletal site measured. Seniors steadily lose bone mass at approximately 0.5% to 1.5% per year as a consequence of an accelerated rate of bone remodeling combined with reduced bone formation.2,16

The major factors (see Tables 99–1, 99–2, and 99–3) influencing bone losses are hormonal status, exercise, aging, nutrition, lifestyle, disease states, medications, and some genetic influences. Nonhormonal risk factors are similar between women and men.

**IMPAIRED BONE QUALITY**

In addition to BMD, the strength of bone is highly affected by the quality of the bone’s material properties and its structure.33 For example, accelerated bone turnover can result in bone loss but can also impair bone quality and the structural integrity of bone by...

BMD, bone mineral density; TSH, thyroid-stimulating hormone; DXA, dual-energy x-ray absorptiometry.
calcium gut absorption. The number of remodeling sites increases, and resorption pits are deeper and inadequately filled by normal osteoblastic function. Significant bone density is lost and bone architecture is compromised. Trabecular bone is most susceptible, leading to vertebral and wrist fractures.

**MALE OSTEOPOROSIS**

Bone physiology of men is under both estrogen and androgen control and influenced by similar hormones and cytokines as female bone. Men are at a lower risk for developing osteoporosis and osteoporotic fractures because of larger bone size, greater peak bone mass, increase in bone width with aging, and fewer falls. Men also do not undergo a period of accelerated bone resorption similar to menopause. However, men have a higher mortality rate after fractures.

The etiology of male osteoporosis tends to be multifactorial with secondary causes (see Tables 99–2 and 99–3) and aging being the most common contributing factors. In young and middle-age men, a secondary cause for bone loss is usually identified, with hypogonadism being the most common. Idiopathic osteoporosis (no known cause) can occur.

**AGE-RELATED OSTEOPOROSIS**

Age-related osteoporosis occurs in seniors, mainly as a result of hormone, calcium, and vitamin D deficiencies leading to an accelerated bone turnover rate in combination with reduced osteoblast bone formation. Hip fracture risk rises dramatically in seniors as a consequence of the cumulative loss of cortical and trabecular bone and an increased risk for falls.

**SECONDARY CAUSES OF OSTEOPOROSIS**

A secondary cause (see Tables 99–2 and 99–3) is identified in more than half of premenopausal and perimenopausal women, about one third of postmenopausal women, and more than two thirds of men. The most common secondary cause for osteoporosis is glucocorticoid therapy, which is discussed later in the Glucocorticoid-Induced Osteoporosis section.

**CLINICAL PRESENTATION**

Table 99–4 outlines the clinical presentation of osteoporosis. Osteoporosis is diagnosed by BMD measurement or presence of a fragility (i.e., low trauma) fracture. Two thirds of patients with a vertebral fracture are asymptomatic or attribute mild lower back pain to “old age.” The other third present with moderate to severe back pain that radiates down their leg after a new vertebral fracture. The pain usually subsides significantly after 2 to 4 weeks; however, residual chronic lower back pain may persist. Multiple vertebral fractures decrease height and sometimes curve the spine (kyphosis or lordosis) with or without significant back pain. Patients who have experienced a nonvertebral fracture frequently present with severe pain, swelling, and reduced function and mobility at the fracture site.

**CONSEQUENCES OF OSTEOPOROSIS**

A fragility fracture is defined as one that occurs as a result of a fall from standing height or less or with minimal to no trauma. Fractures of the vertebrae, hip, forearm, or humerus are considered major osteoporotic fractures. Fractures of the face, skull, fingers, and toes are typically not considered osteoporosis-related. Osteoporotic fractures can lead to increased morbidity and mortality and decreased quality of life. Depression is common because of fear, pain, loss of self-esteem from physical deformity, and loss of independence and mobility.

Symptomatic vertebral fractures can cause significant pain, physical deformity, and adverse health consequences. Patients with severe kyphosis can experience respiratory problems as a result of compression of the thoracic region and gastrointestinal complications, such as poor nutrition, from intraabdominal compression. Women and men who suffer a symptomatic vertebral fracture have a lower survival rate compared with those without a fracture history.

Wrist fractures occur more commonly in younger postmenopausal women and are frequently a result of a fall on an outstretched hand. Negative outcomes include prolonged pain and weakness, and decreased advanced (instrumental) activities of daily living (such as cooking and shopping).

Hip fractures are associated with the greatest increase in morbidity and mortality. In 2006, hip fractures resulted in approximately 330,000 hospital admissions. Nearly 90% of these were in seniors. After a hip fracture, only 50% of patients regain their ability to perform basic activities of daily living, while 20% become nonambulatory. Overall, 3% to 54% of patients die during the initial hospitalization for hip fracture, and 14% to 36% die within 1 year either from complications of the hip fracture or other comorbid disease processes. Men have a twofold higher 1-year mortality rate after hip fracture than women.

Once a low-trauma fracture has occurred, the risk for subsequent fractures goes up exponentially. In subjects with one clinical vertebral fracture, the chance of experiencing any new fracture was 2.8-fold higher, and with two or more vertebral fractures it was 12-fold higher, than for subjects who did not have baseline fractures.
**PATIENT ASSESSMENT**

Bone pain, postural changes (i.e., kyphosis), and loss of height are simple useful physical examination findings. A height loss greater than 1.5 inches (3.8 cm) from the tallest mature height is considered significant and warrants further investigation. Height should be routinely measured using a wall-mounted stadiometer. Proper technique is essential, as can be seen at the National Institutes of Health Web site. A spine radiograph can be obtained to confirm the presence of vertebral fractures. Low bone density or osteopenia reported on routine radiographs is a sign of significant bone loss and requires further evaluation for osteoporosis. In addition to physical examination and laboratory studies (see Table 99–4), patients can be assessed with risk factor assessments, osteoporosis questionnaires, peripheral and central dual-energy x-ray absorptiometry (DXA), and biomarkers.  

**RISK FACTOR ASSESSMENT**

The aim of an initial osteoporosis risk assessment (see Table 99–1) is to identify those patients who are at highest risk for low bone density and who would benefit from further evaluation. Many risk factors for osteoporosis have been identified and are similar for both sexes. The majority of risk factors are predictors of either low BMD (e.g., female sex, ethnicity) or an increased fracture/fall risk (e.g., cognitive impairment, previous falls). The most important risk factors are those associated with fracture risk independent of BMD and fall risk. These major risk factors, in combination with BMD, are used to determine which patients are at greatest risk for fracturing and would benefit most from pharmacologic intervention.

A fracture prediction model used for treatment risk stratification was developed by the World Health Organization (WHO). The WHO model for the United States uses the following risk factors: age, race/ethnicity, sex, previous fragility fracture, parent history of hip fracture, body mass index, glucocorticoid use (ever), current tobacco use, alcohol use of three or more drinks per day, rheumatoid arthritis, and select secondary causes with femoral neck BMD data optional to predict an individual’s percent probability of fracturing in the next 10 years. Other osteoporosis risk assessment tools exist but are usually just used in research versus patient care.  

**SCREENING USING PERIPHERAL BONE MINERAL DENSITY DEVICES**

Peripheral bone density devices that utilize x-ray absorptiometry or quantitative ultrasonometry are helpful as screening tools to determine which patients require further evaluation with central DXA. They should not be used for diagnosis or for monitoring response to therapy. Peripheral DXA of the forearm, heel, and finger uses a low amount of radiation. Heel quantitative ultrasonometry uses sound waves without radiation or need for specialty training.

Because peripheral devices are considerably less expensive than central DXA, easy to use, portable, fast (<5 minutes), and can predict general fracture risk, they are very popular for screening patients at health fairs, community pharmacies, and clinics. No guidelines specifically address who should undergo peripheral bone density screening. However, the best population to screen is younger postmenopausal women without major risk factors for osteoporosis because a low peripheral BMD value in this population would support the need for further testing. The specific peripheral T-score threshold for referral is not universally defined and varies by device. Healthy premenopausal women and patients already identified as being at high risk for osteoporosis based on risk factors, fragility fracture, or secondary causes for osteoporosis, should not be screened but rather referred to a physician for central DXA testing.

**CENTRAL DUAL-ENERGY X-RAY ABSORPTIOMETRY**

BMD measurements at the hip or spine can be used to assess fracture risk, establish the diagnosis and severity of osteoporosis, and sometimes confirm osteoporosis as causative for low-trauma fractures. Central DXA is considered the gold standard for measuring BMD because of its high precision, short scan times, low radiation dose (comparable to the average daily dose from natural background), and stable calibration. Measurement of lumbar spine, proximal femur, and total hip BMD is recommended with the lowest BMD value used for diagnosis. Newer methods, such as micromagnetic resonance imaging, are undergoing investigation to provide measurements of bone quality in addition to bone density.

Several consensus guidelines or position statements are available that discuss which patients should undergo central DXA testing. Most are consistent in recommending central BMD testing for all women aged 65 years or older, men aged 70 years or older, postmenopausal women younger than 65 years of age and men 50 to 69 years old with risk factors for fracture, and patients with an identified secondary cause for bone loss. Patients with a fragility fracture do not need a DXA for an osteoporosis diagnosis, but the results are helpful for determining the severity of osteoporosis and as a baseline for monitoring response to therapy. The DXA results can also help patients make decisions about the need for lifestyle changes and prescription osteoporosis medications. In the absence of a suspected or known secondary cause for osteoporosis or a history of a low-trauma fracture, central BMD testing is not recommended for children, premenopausal women, or men under 50 years of age.

A central DXA BMD report provides the actual bone density value, T-score, and Z-score. The actual bone density value (g/cm²) is most useful for serial monitoring of therapy response, which is typically performed 1 to 2 years after medication initiation. The T-score is used for diagnosis and is a comparison of the patient’s measured BMD to the mean BMD of a healthy, young (20- to 29-year-old), sex-matched white reference population. The Z-score is the number of standard deviations from the mean of the reference population. Ethnic-specific reference databases are not recommended at this time. The Z-score is similar but compares the patient’s BMD to the mean BMD for a healthy sex- and age-matched population. Patient-reported ethnicity should be used for the Z-score if available. The Z-score is sometimes helpful in determining whether a secondary cause for osteoporosis is present and is used for diagnosis in children, premenopausal women, and men younger than 50 years of age.

Using the spine DXA image, an assessment of morphometric vertebral fractures, the vertebral fracture assessment (VFA), can be calculated. Initially a research tool, this analysis of T4 to L4 vertebrae after a DXA is increasing in utilization, especially for seniors. Each vertebra is assessed for compression (wedge, biconcave, and crush) and described as normal or mild, moderate, and severe compression. This result becomes important for treatment decisions in patients with low bone mass.

**LABORATORY TESTS**

Laboratory testing (see Table 99–4) is used to identify secondary causes of bone loss. If a preliminary investigation indicates a possible secondary cause, additional testing might be needed.

Serum 25(OH) vitamin D is the best indicator of total body vitamin D status. Data suggest that serum 25(OH) vitamin D...
concentrations of at least 75 nmol/L or 30 ng/mL (1 ng/mL = 2.5 nmol/L) are necessary to maximize intestinal calcium absorption, minimize secondary hyperparathyroidism, and reduce fracture risk. Although still highly debated, most experts believe that the goal 25(OH) vitamin D concentration should be 30 to 100 ng/mL (75–250 nmol/L); concentrations between 20 and 29 ng/mL (50–72 nmol/L) are insufficient for optimal health, and concentrations below 20 ng/mL (50 nmol/L) would constitute deficiency. Osteomalacia or severe vitamin D deficiency, which is discussed later under the Other Metabolic Bone Disorders section, can occur at concentrations less than 10 ng/mL (25 nmol/L).

Because vitamin D assays are fairly expensive and large interlab assay variability exists, routine vitamin D screening cannot be recommended at this time. However, a 25(OH) vitamin D concentration should be considered in anyone at higher risk for low vitamin D (e.g., seniors, patients who are obese or who have minimal sun exposure, insufficient vitamin D intake, dark pigmented skin, or certain medical conditions, or are on medications known to affect vitamin D metabolism), and patients with low bone density, history of a low-trauma fracture or frequent falls, or history of unexplained muscle weakness and/or bone pain.

**BONE TURNOVER MARKERS**

Urine and serum bone turnover markers are either enzymes involved in bone metabolism, and patients with low bone density, history of a low-trauma fracture or frequent falls, or history of unexplained muscle weakness and/or bone pain.

**DIAGNOSIS OF OSTEOPOROSIS**

The diagnosis of osteoporosis is based on a low-trauma fracture or central hip and/or spine DXA using WHO T-score thresholds. Osteopenia or low bone mass is a T-score between −1 and −2.5, and osteoporosis is a T-score at or below −2.5. Although these definitions are based on data from postmenopausal white women, they are applied to perimenopausal women, men age 50 years and older, and other race/ethnic groups. The diagnosis of osteoporosis in children, premenopausal women, and men under 50 years of age should be based on a Z-score at or below −2.0 in combination with other risk factors or fracture.

**PREVENTION AND TREATMENT**

**Osteoporosis**

The foundation for osteoporosis prevention and treatment is a bone healthy lifestyle beginning at birth and continuing throughout life. Supplements and medications are used when lifestyle habits are suboptimal and/or osteoporosis has developed.

**DESIRED OUTCOMES**

The primary goal of osteoporosis management should be prevention. Optimizing skeletal development and peak bone mass accrual in childhood, adolescence, and early adulthood will ultimately reduce the future incidence of osteoporosis. Once low bone mass or osteoporosis develops, the objective is to stabilize or improve bone mass and strength and prevent fractures. In patients who have already suffered osteoporotic fractures, reducing pain and deformity, improving functional capacity, improving quality of life, and reducing future falls and fractures are the main goals.

**GENERAL APPROACH TO PREVENTION AND TREATMENT**

1. A bone-healthy lifestyle should begin at birth and continue throughout life. Insuring adequate intakes of calcium and vitamin D along with other bone-healthy lifestyle practices are the first steps in prevention and treatment. Recent guidelines/position statements recommend considering prescription therapy in any postmenopausal woman or man age 50 years and older presenting with one of the following scenarios: a hip or vertebral fracture; T-score of −2.5 or lower; or low bone mass (T-score between −1.0 and −2.5) with a secondary cause associated with a high risk for fracture, a history of prior fracture, a 10-year probability of hip fracture of 3% or more, or a 10-year probability of any major osteoporosis-related fracture of 20% or more. Figure 99–3 provides an osteoporosis management algorithm for postmenopausal women and men 50 years and older that incorporates both nonpharmacologic and pharmacologic approaches.

**NONPHARMACOLOGIC THERAPY**

Nonpharmacologic therapy, referred to as a bone-healthy lifestyle, includes a nutritious diet, smoking cessation, minimal alcohol intake, exercise, and fall prevention. Consumers might opt for self-care and use the Internet for decisions about osteoporosis management, especially regarding options that are natural or available without a prescription. Since Internet information can be wrong or misleading, consumers should discuss nonprescription medication choices with a healthcare professional.

**Diet**

Overall, a diet well balanced in nutrients and minerals and limited in alcohol, caffeine, and carbonated cola beverages is important for bone health.

**Calcium**

Data clearly indicate that adequate calcium intake is necessary for the development of bone mass during growth and for its maintenance throughout life. Adequate calcium intake is an essential component of all osteoporosis prevention and treatment strategies. Table 99–3 summarizes the recommended intakes for calcium based on age. Achieving daily calcium requirements from calcium-containing foods, which also contain other essential nutrients, is preferred. Milk and other dairy products have the highest amount of calcium per serving and are available in low-fat options. Some food sources are absorbed well but have low elemental calcium content (e.g., broccoli). Other foods contain oxalic acid (e.g., spinach) or phytic acid (e.g., wheat bran) that bind calcium contained in the food, decreasing its absorption. For example, to get the same amount of calcium in one 8-ounce (~240 mL) glass of milk, one would need to eat 2.25 cups (~530 mL) of cooked broccoli or 8 cups (~1900 mL) of cooked spinach.

People should be encouraged to evaluate their food and beverage intake to determine if they are receiving adequate intakes.
To calculate the amount of calcium in a serving of food, consumers can add a zero to the percentage of the daily value listed on food labels. For example, a serving of milk (8 oz. [~240 mL]) has 30% of the daily value of calcium. This translates to 300 mg calcium per serving.

Approximately 25% of the U.S. population has some level of lactose intolerance, with the incidence in Asian (80%) and African American (50%) populations being much higher than in whites (10%).57 Lactose-intolerant patients have several options, including products containing lactase (Lactaid), lactose-reduced milk, lactose-free milk, calcium-fortified soy milk, certain aged cheeses, or yogurt products containing lactase (Lactaid), lactose-reduced milk, lactose-free milk, calcium-fortified soy milk, certain aged cheeses, or yogurt.

Vitamin D

Table 99-5 lists the recommended adequate intakes for Vitamin D.54,58,59 The three main sources of vitamin D are sunlight, diet, and supplements. Websites can be used to identify the few foods high in vitamin D.64 To calculate the amount of vitamin D in a serving of food, multiply the % daily value of vitamin D listed on the food label by 4 (e.g., 20% vitamin D = 80 units). Because few foods are naturally high or fortified with vitamin D, most people, especially seniors, require supplementation.

Other Nutrients and Minerals

Vitamin K is a cofactor for carboxylation (activation) of proteins, such as osteocalcin, which are involved in bone formation. Several studies have demonstrated that vitamin K deficiency can contribute to bone loss and an increased risk for fractures.62,63 Studies evaluating the benefits of vitamin K supplementation are conflicting, with some demonstrating reduced
bone loss and fracture risk. More data are needed before recommending routine supplementation. Some calcium supplements already contain vitamin K. This is important to note for patients receiving warfarin therapy.

Minimal to no data exist for other nutrients and minerals such as potassium, boron, and magnesium. Until more data are available, taking a multivitamin once daily and consuming a healthy diet, following the U.S. Department of Agriculture food pyramid recommendations for daily fruit and vegetable intake, should provide an adequate intake of these vitamins and minerals for general bone health.

**Dietary Soy** Isoflavone phytoestrogens are plant-derived compounds that possess weak estrogen agonist and antagonist effects. The most common source for isoflavone is dietary soy products. Genistein is the most abundant and biologically active isoflavone in soybeans. The evidence supporting a positive bone benefit from soy protein (isoflavone) intake is conflicting, with some studies showing improvements in bone density with larger isoflavone intakes. Only one study has evaluated the association between soy intake and fracture risk. This population-based prospective cohort study from China demonstrated that higher isoflavone intake was associated with a significantly lower risk of fractures. Since isoflavones from soy foods appear safe, patients can be encouraged to increase their intake, but true benefits on fracture are not clear. More information is needed on the safety of isoflavone supplements, especially in women with breast cancer.

**Alcohol** Alcohol consumption in moderation is not associated with an increased risk for osteoporosis or fractures. Excessive alcohol intake increases osteoporosis risk because of poor nutrition, impaired calcium and vitamin D metabolism, and an increased risk for falls. According to 2005 dietary guidelines, alcohol consumption should not exceed one drink per day for women and two drinks per day for men.

**Caffeine** Although results are conflicting, excessive caffeine consumption is associated with increased calcium excretion, increased rates of bone loss, and a modestly increased risk for fracture. Ideally, caffeine consumption should be limited to two servings or less per day. Moderate caffeine intake (two to four servings per day) should not be a concern if adequate calcium intake is achieved daily.

**Carbonated Beverages** Consumption of cola beverages, even without caffeine, is associated with decreased BMD and increased fracture risk; however, data are conflicting. The phosphoric acid content of cola beverages is thought to contribute to bone loss by altering calcium balance. This effect is compounded by decreased milk consumption and consequent reductions in calcium intake with the increase in carbonated beverage intake seen in the United States.

**Smoking Cessation** Counseling patients of all ages on smoking cessation can help to optimize peak bone mass, minimize bone loss, and ultimately reduce fracture risk. Cigarette smoking is an independent risk factor for osteoporosis and is associated with up to an 80% increased relative risk for hip fracture. The effect is dose and duration dependent. A decrease in sex hormone concentrations, reduced intestinal calcium absorption, a direct toxic effect on osteoblasts, and detrimental effects of smoking on neurovascular function have been implicated for the negative bone effects.

**Exercise** Physical activity or exercise is an important nonpharmacologic approach to preventing osteoporotic fractures. Exercise can decrease the risk of falls and fractures by stabilizing bone density and improving muscle strength, coordination, balance, and mobility. Physical activity is especially important early in life as lack of exercise during growth can lead to suboptimal loading/straining, decreased stimulation of bone deposition, and a subsequently reduced peak bone mass. All patients who are medically fit should be encouraged to perform a moderate-intensity weight-bearing activity (e.g., walking, jogging, golf, stair climbing) for at least 30 minutes most days of the week and a resistance activity (e.g., weight machines, free weights, or elastic bands) at least twice per week for 20 to 30 minutes.

**Fall Prevention** Risk of falling increases with advanced age predominantly as a result of balance, gait, and mobility problems, poor vision, reduced muscle strength, impaired cognition, multiple medical conditions (e.g., stroke, Alzheimer’s dementia, Parkinson disease), and polypharmacy. Psychoactive medications such as benzodiazepines, antidepressants, antipsychotics, sedative-hypnotics, and opioids have been strongly associated with falls.

The ability to adapt to falls also decreases with aging. Seniors are more likely to sustain a hip or pelvic fracture because they tend to fall backward or sideways instead of forward.

Because of the link between falls and fractures, patients who experience an acute fall, have more than two falls per year, or have walking or balance problems should have a falls assessment and potentially a multidisciplinary intervention program (e.g., falls clinic). Intervention programs are documented to decrease falls, fractures, other injuries, and nursing home and hospital admissions.

Patients should be educated on personal and home safety options to decrease falls. Websites provide great patient education materials with solutions for commonly observed safety problems. Medication profiles should also be reviewed for any unnecessary medications that can affect cognition and balance and potentially increase fall risk. Consideration should be given to replacing high-risk medications with safer alternatives. Adequate vitamin D intake has been associated with reduced falls. Maintenance of a regular individualized exercise program, such as tai chi, should be recommended to improve body strength, balance, and agility.

Other recommendations include resolving vision, blood pressure, heart rate/rhythm, and foot problems and using proper footwear.

External hip protectors are specialized undergarments designed to pad the area surrounding the hip, decreasing the force of impact from a sideways fall. Conflicting results and poor adherence limit their use.

**PHARMACOLOGIC THERAPY**

Because nonpharmacologic interventions alone are frequently insufficient to prevent or treat osteoporosis, medication therapy is often necessary. Table 99-6 describes fracture and BMD effects, and Table 99-7 describes important aspects of common osteoporosis medications. These medications should always be combined with a bone-healthy lifestyle.

**MEDICATION**

**Treatments of First Choice** Combined with adequate calcium and vitamin D intakes, bisphosphonates are the prescription medication of choice, with teriparatide, denosumab, raloxifene, and calcitonin considered alternative agents. Duration of bisphosphonate therapy has not been defined, but safety data exist for periods of 7 to 10 years. Short-term (18–24 months) teriparatide is usually reserved for

**Published Guidelines and Treatment Protocols**

The 2008 National Osteoporosis Foundation’s clinician’s guide and the 2010 North American Menopause Society’s position statement provide guidance on osteoporosis prevention and treatment strategies. Some additional subspecialty guidelines exist (e.g., osteoporosis and gastrointestinal [GI] diseases) but will not be covered here. Applying the National Osteoporosis Foundation’s guidelines to a large clinical database, researchers found that about 72% of women ≥65 years old and 93% of women ≥75 years old would be eligible for treatment. Even with guidelines and algorithms, many patients are not being evaluated nor receiving appropriate osteoporosis therapy, even after a hip fracture.

**Antiresorptive Therapies**

Antiresorptive therapies include calcium, vitamin D, bisphosphonates, estrogen agonists antagonists (known previously as selective estrogen receptor modulators or SERMs), calcitonin, denosumab, estrogen, and testosterone.

**Calcium Supplementation**

Calcium imbalance can result from inadequate dietary intake, decreased fractional calcium absorption, or enhanced calcium excretion. Adequate calcium intake (see Table 99–3) is considered the standard for osteoporosis prevention and treatment and should be combined with vitamin D and osteoporosis medications when needed. Supplemental calcium intake will be needed in the majority of people with or at risk for osteoporosis as survey data indicate that the average U.S. female and male diet contains only 660 and 797 mg calcium per day, respectively.

**Efficacy.** Although calcium increases BMD, fracture prevention is minimal. Almost all trials and observational studies showed the children and adults with the higher calcium intakes had greater increases or maintenance of BMD compared to BMD losses with placebo. Calcium’s BMD effects are less than other antiresorptive and formation osteoporosis medications. Fracture prevention is only documented with concomitant vitamin D therapy. Some data support other calcium benefits such as decreased blood pressure, cholesterol, and colorectal cancer risk.

**Adverse Events/Precautions.** Calcium’s most common adverse reaction, constipation, can first be treated with increased water intake, dietary fiber, and exercise. If still unresolved, smaller and...
Vitamin D Supplementation

Vitamin D intake is critical for the prevention and treatment of osteoporosis because it maximizes intestinal calcium absorption. Given its safety, low cost, and other benefits of vitamin D, no patient should have an inadequate intake.

**Efficacy.** Data show that higher dose vitamin D supplementation is needed for fracture and fall prevention. Based on a meta-analysis, higher doses of vitamin D (>400 units daily) decreased nonvertebral and hip fractures by approximately 20%.41 These results are consist with a previous meta-analysis showing doses of 700 to 800 units reduced fractures, but doses of 400 units per day did not.42 Some but not all studies support vitamin D decreasing falls.74,75 Conflicting results between studies are thought to be a result of differences in vitamin D dosing, concomitant calcium administration, adherence, and baseline vitamin D status of subjects.

Vitamin D has other potential nonskeletal benefits. Improvement in muscle strength and cardiovascular function, decreased cancer risk (e.g., breast, colon, and prostate cancers), and positive immunomodulatory effects (e.g., multiple sclerosis, type 1 diabetes, rheumatoid arthritis) have been proposed.21

**Administration.** Seniors and patients being treated for osteoporosis should take at minimum 800 to 1,000 units of vitamin D through food and supplementation with a goal to maintain their 25(OH) vitamin D concentration within the sufficient range (i.e., ≥30 ng/mL [≥75 nmol/L]).22 Several experts believe higher doses (i.e., up to 4,000 units of vitamin D daily) should be recommended, especially in certain populations.27 In one Canadian study, 1,000 units vitamin D daily only resulted in 35% of seniors in the therapeutic range (>30 ng/mL [≥75 nmol/L]), whereas 4,000 units per day resulted in 88% in the therapeutic range.28 In another study, 3,800 units were required to achieve and maintain therapeutic ranges when patients’ initial 25(OH) vitamin D concentration was at least 22 ng/mL (55 nmol/L); 5,000 units were required for those with a 25(OH) vitamin D concentration less than 22 ng/mL (55 nmol/L).24

Whether cholecalciferol (vitamin D₃) is more efficient than ergocalciferol (vitamin D₂) at raising 25(OH) vitamin D concentrations is controversial, with data supporting both arguments.72,85 Usual supplementation is with daily nonprescription cholecalciferol vitamin D products. However, higher-dose prescription ergocalciferol regimens administered weekly, monthly, or quarterly are used for replacement and maintenance therapy.22 Approximately 100 units vitamin D daily will raise the 25(OH) vitamin D concentration by 1 ng/mL (2.5 nmol/L). More than one multivitamin or large doses of cod liver oil daily are no longer advocated because of the risk of hypervitaminosis A, which can increase bone loss. Because the half-life of vitamin D is about 1 month, approximately 3 months of therapy are required before a new steady state is achieved and a repeat 25(OH) vitamin D concentration can be obtained.

Individuals with deficient concentrations of vitamin D are at risk for osteomalacia. Their management is discussed in Other Metabolic Bone Diseases later in the chapter. In patients with disorders affecting vitamin D absorption (e.g., celiac disease, cystic fibrosis, or Crohn’s disease), higher doses and more frequent monitoring are required. In patients with severe hepatic or renal disease, the activated form of vitamin D (calcitriol) might be more appropriate. However, new information with regard to vitamin D’s nontoxic effects suggests replacement with both cholecalciferol and calcitriol might be needed.23

**Bisphosphonates** Bisphosphonates mimic pyrophosphate, an endogenous bone resorption inhibitor.46 Bisphosphonate antiresorptive activity results from blocking prenylation and inhibiting guanosine triphosphate-signaling proteins, which lead to decreased osteoclast maturation, number, recruitment, bone adhesion, and life span. Their various R2 side chains produce different bone binding, persistence, and affinities; however, the
resulting clinical significances are not known. All bisphosphonates become incorporated into bone, giving them long biologic half-lives of up to 10 years. Alendronate, risedronate, and intravenous zoledronic acid are FDA indicated for postmenopausal, male, and glucocorticoid-induced osteoporosis (see Table 99–7). Intravenous and oral ibandronate are indicated only for postmenopausal osteoporosis.

**Efficacy.** Of the antiresorptive agents, bisphosphonates consistently provide some of the higher fracture risk reductions and BMD increases (see Table 99–6).

Fracture clinical trial data only exist for daily oral bisphosphonate and annual intravenous therapy, not weekly, monthly, or quarterly regimens. Although hip fracture reduction was not seen with daily oral ibandronate, the hip fracture incidence in the placebo group was low, suggesting the study might have been underpowered. Fracture reductions are demonstrated as early as 6 months, with the greatest fracture reduction seen in patients with lower initial BMD and in those with the greatest BMD changes with therapy. Although comparative fracture prevention trials do not exist, no differences between oral bisphosphonates and fractures were found based on claims data.

Annual intravenous zoledronic acid has documented both secondary fracture prevention and a decrease in mortality in the treated group. Zoledronic acid has also been documented to decrease bone loss and fractures for patients receiving certain chemotherapy.

BMD increases with bisphosphonates are dose dependent and greatest in the first 6 to 12 months of therapy. Small increases continue over time at the lumbar spine, but plateau after 2 to 5 years at the hip. After discontinuation, the increased BMD is sustained for a prolonged period of time that varies depending on the bisphosphonate used. Weekly alendronate, weekly and monthly risedronate, and monthly oral and quarterly intravenous ibandronate therapy produce equivalent BMD changes to their respective daily regimens. Weekly alendronate therapy increases BMD more than weekly risedronate therapy; however, no evidence indicates that this difference would equate to greater fracture efficacy. Weekly alendronate and monthly ibandronate produced similar BMD effects.

The BMD increases with alendronate, risedronate, and zoledronic acid in men are similar to those in postmenopausal women. Because of a lack of fracture data from pivotal trials in men, bisphosphonates are only FDA indicated to increase BMD, not to reduce fracture risk in men. Pooled analysis of risedronate studies did document fracture prevention in men, and alendronate has been shown to decrease radiographic but not clinical vertebral fractures.

### Adverse Events/Precautions

**Adverse Events/Precautions.** If oral bisphosphonates are prescribed correctly and the patient takes them correctly, their adverse effects are minimal. Patients with creatinine clearances less than 30 to 35 mL/min (0.50–0.58 mL/s), who have serious GI conditions (abnormalities of the esophagus that delay emptying, such as stricture or achalasia), or who are pregnant should not take bisphosphonates. Some experts suggest bisphosphonates can be used in select patients with decreased renal function (see Chapters 52 and 53 on Chronic Kidney Disease). Weekly and monthly therapies have similar common but less serious GI effects (perforation, ulceration, GI bleeding) than daily therapy. The GI event rates were not increased with concomitant nonsteroidal anti-inflammatory medication use. If GI adverse events occur, switching to a different bisphosphonate might resolve the problem. Patients should be encouraged to discuss GI complaints with a healthcare provider. Intravenous ibandronate and zoledronic acid can be used for patients with GI contraindications or intolerances to oral bisphosphonates. Other common bisphosphonate adverse effects include injection reactions and musculoskeletal pain. Local injection-site reactions and acute phase reactions (e.g., fever, flu-like symptoms) can occur but usually diminish with subsequent injections. If severe musculoskeletal pain occurs, the medication can be discontinued for a short term or permanently.

Rare adverse effects include osteonecrosis of the jaw and subtrochanteric femoral (atypical) fractures. Osteonecrosis of the jaw (ONJ; black box warning) occurs more commonly in patients with cancer, chemotherapy, radiation, and or glucocorticoid therapy receiving higher-dose intravenous bisphosphonate therapy. With oral therapy, about 1 in 100,000 patients might get ONJ. When possible, major dental work should be completed before bisphosphonate initiation. For patients already on therapy, some practitioners withhold bisphosphonate therapy during and after major dental procedures, but no data exist to support any beneficial effect of such practice. For patients with rare and unusual bone fractures while on long-term bisphosphonates, a metabolic bone disease workup should be conducted.

**Administration.** Before bisphosphonates are used, and especially before intravenous administration, the patient’s serum calcium concentrations must be normal. Because bioavailability is very poor for bisphosphonates (<1% to 5%) and to minimize GI side effects, each oral dose should be taken with at least 6 ounces of plain tap water (not coffee, juice, mineral water, or milk) at least 30 (60 for ibandronate) minutes before consuming any food, supplements (including calcium and vitamin D), or medications. The weekly, raspberry-flavored, oral solution needs to be taken with only 2 ounces (~60 mL) of water and can be used for patients with swallowing difficulties (e.g., after stroke, tube feeding). The patient should also remain upright (i.e., either sitting or standing) for at least 30 minutes after alendronate and risedronate and 1 hour after ibandronate administration. A patient who misses a weekly dose can take it the next day. If more than 1 day has lapsed, that dose is skipped until the next scheduled ingestion. If a patient misses a monthly dose, it can be taken up to 7 days before the next administration.

The intravenous products need to be administered by a healthcare provider. The quarterly ibandronate injection comes as a prefilled syringe (3 mg/mL) kit with a butterfly needle. The injection is given intravenously over 15 to 30 seconds. The injection can also be diluted with dextrose 5% in water or normal saline and used with a syringe pump. Once-yearly administration of zoledronic acid should be infused over at least 15 minutes with a pump. Acetaminophen or ibuprofen can be given to decrease acute phase reactions.

Although these medications are effective, adherence is poor and results in decreased effectiveness. Although most patients
prefer once-weekly or once-monthly bisphosphonate administration to daily therapy, adherence is still a problem. Even after a hip fracture, bisphosphonate persistence is suboptimal. For patients with adherence issues, the monthly e-mails or postcards sent by the ibandronate manufacturer might be helpful. Intravenous ibandronate and zoledronic acid could be used as replacements if cost is not an issue. Weekly alendronate plus vitamin D can potentially help to ensure better adherence with vitamin D intake.

**Mixed Estrogen Agonists/Antagonists**

Raloxifene, a second-generation mixed estrogen agonist/antagonist (EAA) approved for prevention and treatment of postmenopausal osteoporosis, has estrogenic agonist actions in bone but antagonist actions in breast and uterine tissue (see Table 99–7). Bazedoxifene with and without conjugated equine estrogens and lasofoxifene are newer second-generation EAAs that might be approved soon.

**Efficacy.** Raloxifene decreases vertebral fractures and increases spine and hip BMD, but to a lesser extent than bisphosphonates (see Table 99–6). Eight-year data support long-term effects and safety in postmenopausal women. After raloxifene discontinuation, the medication effect is lost, with bone loss returning to age- or disease-related rates. For women with severe osteoporosis, particularly when hip fracture risk reduction is desired, a bisphosphonate might be a better choice. Since estradiol is important for bone health in men, some preliminary data have documented benefits of raloxifene in men with hypogonadism and prostate cancer.

Raloxifene has additional benefits that might influence its selection. Raloxifene has an FDA-approved indication for invasive breast cancer risk reduction. Thus in a subset of women, this additional benefit might warrant raloxifene use for dual osteoporosis and breast cancer prevention.

Some of the investigational EAAs have also documented breast cancer risk prevention. Raloxifene causes some positive lipid effects (decreased total and low-density lipoprotein cholesterol, neutral effect on high-density lipoprotein cholesterol, slightly increased triglycerides). However, no reduction in cardiovascular effects was demonstrated in the RUTH (Raloxifene Use for the Heart) or MORE-CORE (Multiple Outcomes with Raloxifene study and its continuation) trials.

**Adverse Events/Precautions.** Hot flushes occur with a greater likelihood in women recently finishing menopause or discontinuing estrogen therapy. Raloxifene rarely causes endometrial bleeding. Raloxifene is contraindicated for women with an active or past history of venous thromboembolic event. Therapy should be stopped if a patient anticipates extended immobility.

In large trials, no change in overall death, cardiovascular death, or overall stroke incidence was seen; however, a slight increase in fatal stroke was documented, resulting in a black box warning. Women at high risk for a stroke (e.g., Framingham stroke risk score ≥13) or coronary events and those with known coronary artery disease, peripheral vascular disease, atrial fibrillation, or a prior history of cerebrovascular events might not be good candidates for this medication.

**Administration.** Similar to bisphosphonates, adherence and persistence problems exist.

**Calcitonin**

Calcitonin is an endogenous hormone released from the thyroid gland when serum calcium is elevated. The prescription product contains salmon calcitonin, which is more potent and longer lasting than the mammalian form. Calcitonin is FDA indicated for osteoporosis treatment for women who are at least 5 years past menopause (see Table 99–7). Because efficacy is less robust than the other antiresorptive therapies, calcitonin is reserved as third-line treatment. Intermittent nasal regimens and an oral product are being explored.

**Efficacy.** Only vertebral fractures have been documented to decrease with intranasal calcitonin therapy (see Table 99–6). Calcitonin does not consistently affect hip BMD and does not decrease hip fracture risk.

Calcitonin might provide pain relief to some patients with acute vertebral fractures, about a 2.5-point change on a visual analog scale. If used, calcitonin should be prescribed for short-term (4 weeks) treatment and should not be used in place of other more effective and less expensive analgesics nor should it preclude the use of more appropriate osteoporosis therapy.

**Administration.** Subcutaneous administration with 100 units daily is available but rarely used because of more adverse effects and costs.

**Denosumab Therapy**

Recently approved; see investigational agents, Tables 99–6 and 99–7, Figure 99–3, and addendum.

**Estrogen Therapy**

Although estrogens are FDA indicated for prevention of osteoporosis, they should only be used short-term in women who need estrogen therapy for the management of menopausal symptoms as the risks of estrogen therapy outweigh the bone benefits. Even though the Women’s Health Initiative trials only assessed one dose of conjugated equine estrogens, most clinicians extrapolate the results to all postmenopausal estrogen therapies until data indicate otherwise.

**Efficacy.** Hormone therapy (HT)—that is, estrogen with (EPT) or without (ET) a progestogen—significantly decreases fracture risk (see Table 99–6). Increases in BMD are less than with bisphosphonates, denosumab, or teriparatide, but greater than with raloxifene and calcitonin. Oral and transdermal estrogens at equivalent doses and continuous or cyclic HT regimens have similar BMD effects. Effect on BMD is dose dependent, with some benefit seen with lower estrogen doses; however, fracture risk reduction has not been demonstrated with the lower doses. When HT is discontinued, bone loss accelerates and fracture protection is lost.

**Adverse Events/Precautions/Administration.** The lowest effective HT dose that prevents and controls menopausal symptoms is used and discontinued as soon as possible. A complete discussion of adverse events, precautions, and administration for all ET and estrogen and progestogen combination products can be found in Chapter 91.

**Testosterone**

Decreased testosterone concentrations are seen with certain gonadal diseases, eating disorders, glucocorticoid therapy, oophorectomy, menopause, and andropause.

**Efficacy.** A few studies of testosterone or methyltestosterone replacement in men and women, respectively, have demonstrated increases in BMD, but no data on fracture prevention exist. Adding alendronate to testosterone therapy in hypogonadal men improved BMD benefits. Testosterone replacement should not be used solely for the prevention or treatment of osteoporosis, but it might be beneficial to reduce bone loss in patients needing therapy for hypogonadal symptoms or for women with low libido.

**Adverse Events/Precaution/Administration.** Patients and partners of those using testosterone gel products should be evaluated frequently for adverse events.

**Anabolic Therapies**

Currently teriparatide is the only available medication that increases bone formation.

**Teriparatide**

Teriparatide is a recombinant product representing the first 34 amino acids in human PTH (see Table 99–7). Teriparatide increases bone formation, the bone remodeling rate, and osteoblast number and activity. Both bone mass and
architecture are improved. Teriparatide is FDA indicated for postmenopausal women, men, and patients on glucocorticoids who are at high risk for fracture. For example, patients who have a history of osteoporotic fracture, multiple risk factors for fracture, very low bone density (e.g., T-score < −3.5), or have failed or are intolerant of previous bisphosphonate therapy could be candidates for PTH therapy. Human PTH (1-31), oral PTH, intranasal PTH, and once-weekly subcutaneous teriparatide administration are being investigated.

**Efficacy.** Teriparatide reduces vertebral and nonvertebral fracture risk in postmenopausal women (see Table 99-6); however, no fracture data are available in men or for patients taking glucocorticoids. Lumbar spine BMD increases are greater than other osteoporosis medications. Although wrist BMD is decreased, wrist fractures are not increased. Discontinuation of teriparatide therapy results in a decrease in BMD, which can be alleviated with subsequent antiresorptive therapy.

Using a second course of teriparatide is controversial. Some advocate no second course. One study found that a second course of teriparatide increased BMD but not to the extent with the first course. Adverse Events/Precautions. Transient hypercalcemia rarely occurs. A trough serum calcium concentration is recommended 1 month after initiation of therapy. If high (>10.6 mg/dL [>2.65 mmol/L]), calcium intake should be decreased.

Because of an increased incidence of osteosarcoma in rats, teriparatide contains a black box warning against use in patients at increased baseline risk for osteosarcoma (e.g., Paget’s bone disease, unexplained elevations of alkaline phosphatase, pediatric patients, young adults with open epiphyses, or patients with prior radiation therapy involving the skeleton). In addition, teriparatide should not be used in patients with hypercalcemia, metabolic bone diseases other than osteoporosis, metastatic or skeletal cancers, or premenopausal women of child-bearing potential.

**Administration.** Teriparatide is commercially available as a pre-filled “pen” delivery device. The pen must be kept refrigerated and can be used immediately after removing from the refrigerator. The subcutaneous injection is delivered to the thigh or abdominal area with site rotation. The administration of the first dose should take place with the patient either sitting or lying down in case orthostatic hypotension occurs. The pen must be discarded 28 days after the initial injection. The patient should be reeducated on correct use with each pen refill.

Teriparatide is the most expensive osteoporosis therapy. Prior authorization may be required. Special arrangements need to be made when patients travel, especially on airplanes.

**Combination Therapy**

Combination antiresorptive and anabolic therapies have been evaluated with conflicting results. Greater increases in BMD have sometimes been demonstrated when a less potent antiresorptive agent, raloxifene or HT, was used with PTH, whereas a blunting of the BMD effect has been seen when combined with alendronate. The effects of other bisphosphonates in combination with PTH might be different as some newer literature is beginning to reveal. This therapeutic issue is still being explored.

Because there is no clear benefit (no documented increased fracture prevention) and there is potential for increased cost, adverse effects, and nonadherence, combination therapy is not recommended.

**Investigational Therapies**

Besides the aforementioned investigational products, new medication classes are also being developed.

**RANKL Inhibitors** Denosumab is a fully human monoclonal antibody that binds to RANKL, blocking its ability to bind to its receptor activator of nuclear factor kappa B (RANK) on the surface of osteoclast precursor cells and mature osteoclasts (see Table 99-7). Denosumab inhibits osteoclastogenesis and increases osteoclast apoptosis.

Denosumab was recently approved for select postmenopausal women (see Figure 99-3) and is still being evaluated for chemotherapy-induced osteoporosis. Denosumab 60 mg subcutaneous injection every 6 months for 3 years significantly decreased vertebral fractures by 68%, nonvertebral fractures by 20%, and hip fractures by 40% in postmenopausal women. The same dose improved BMD and decreased new vertebral fractures without significant changes in nonvertebral or clinical vertebral fractures in men receiving androgen deprivation therapy. The BMD effects are at least similar to weekly alendronate and can increase BMD in patients with prior alendronate therapy; however, these studies did not evaluate any fracture outcomes. Activity appears to dissipate upon medication discontinuation.

Adverse effects include back, extremity, and musculoskeletal pain, hypercholesterolemia, cystitis, decreased serum calcium, and skin problems, which were generally similar to placebo or weekly alendronate. Rare, serious adverse effects include serious infections, osteonecrosis of the jaw, and bone turnover suppression.

**Other Investigational Medication Classes** Additional new classes of medications are beginning to show promise.

Although injectable OPG, a competitive inhibitor of RANKL, blocked osteoclastic differentiation and decreased bone resorption biomarkers in phases I and II, further development has ceased. However, agents to enhance endogenous OPG, decrease RANKL production, or block RANKL binding to receptor activator of nuclear factor kappa B are being developed.

Agents to block osteoclast attachment (AVβ3 integrin receptor antagonists), inhibit bone matrix degradation (cathepsin K inhibitors, e.g., odanacatib and relacatib), or change osteoclast and osteocyte cell structure (antisclerostin monoclonal antibodies) are in phase I, II, and III clinical trials.

Strontium ranelate and tibolone are approved in Europe, and the latter agent is approved in Canada. Most likely, these two medications will not be marketed in the United States.

**VERTEBROPLASTY AND KYPHOPLASTY**

Sometimes patients with debilitating pain between 6 and 52 weeks after a vertebral fracture might undergo vertebroplasty or kyphoplasty during which bone cement is injected into the fractured vertebral space. The procedure stabilizes the damaged vertebrae and reduces pain in 70% to 95% of patients. However, not all studies have documented benefit of this procedure, and concerns about long-term outcomes are surfacing. Adverse events are uncommon but include cement leakage into the spinal column, which can result in complicating nerve damage, and vertebral fracturing around the cement.

**SPECIAL POPULATIONS**

**CHILDREN**

Osteoporosis is a particular threat to all age groups and in some subgroups because of genetic abnormalities, diseases, and medications.
are the main contributors to osteoporosis in children (Tables 99–2 and 99–3). Idiopathic juvenile osteoporosis is a condition that can develop in previously healthy children (mostly between 8 and 12 years of age) and is only diagnosed after the exclusion of all other possible causes of osteoporosis. It can spontaneously resolve after 3 to 5 years, but sequelae can persist into adulthood. Although the pathogenesis is unknown, reduced osteoblastic bone formation mainly in trabecular regions appears to play a primary role.

The diagnosis and treatment of osteoporosis in children and adolescents is challenging. No guidelines or consensus recommendations exist. The International Society for Clinical Densitometry’s official position is that the diagnosis of osteoporosis in children (<20 years of age) requires the presence of a clinically significant fracture history (long bone fracture of the lower extremity, vertebral compression fracture, or two or more long bone fractures of the upper extremities) in combination with low bone mass. Low bone mass is defined as a Z-score below −2.0 (adjusted for body size and ethnicity/race) using central DXA of the spine or total body.

After correcting any underlying causes and instituting a bone-healthy lifestyle, pharmacologic treatment should be considered for children with low bone mass and low trauma fractures. Several small studies, mostly evaluating the intravenous bisphosphonate pamidronate or oral alendronate, have demonstrated increases in BMD. No studies have demonstrated fracture efficacy in this population. The optimal medication, dose, and duration of therapy are unknown, and more safety data are needed. A major concern with bisphosphonates is their effect on longitudinal bone growth and modeling; however, fracture healing, skeletal growth/maturation, or the appearance of growth plates does not appear to be impaired. Teriparatide cannot be used in children as it has a black box warning indicating an increased risk for osteosarcoma.

PREMENOPAUSAL WOMEN

Clinically significant bone loss and fractures in healthy premenopausal women are rare. Approximately 15% of healthy premenopausal women will have low BMD as a normal variation of peak bone mass. Low peak bone mass is a major risk factor for postmenopausal osteoporosis and fractures but thus far is not a predictor of an increased risk for fractures in the premenopausal years. This might be a result of better bone architecture contributing to better bone strength in younger women.

Routine bone density screening and testing are not cost effective and should not be performed in healthy premenopausal women. No evidence supports that identifying low bone density in healthy premenopausal women results in improved bone-healthy lifestyle practices nor does any evidence exist to support that pharmacologic treatment will reduce future fracture risk in this population.

Most premenopausal women with osteoporosis (Z-score < −2.0) or a history of low-trauma fracture have an identifiable secondary cause (see Tables 99–2 and 99–3). Therefore, premenopausal women presenting with a history of low-trauma fracture or with a suspected secondary cause for osteoporosis should undergo central DXA testing; if BMD is low, the patient should be considered for pharmacologic therapy. Women with an unidentified cause for osteoporosis and no history of fracture should be treated with a bone-healthy lifestyle and watchful waiting.

Pharmacologic therapy for osteoporosis should be used with caution in premenopausal women as efficacy and safety have not been adequately demonstrated. The oral bisphosphonates, intravenous ibandronate, calcitomin, and teriparatide are in pregnancy category C. Zoledronic acid is in pregnancy category D. Raloxifene is in pregnancy category X.

Bisphosphonates are incorporated into the bone matrix and slowly released over time. A theoretical concern is a risk for fetal harm with pregnancies that occur during and after therapy has been stopped. While limited case reports have documented healthy infants after bisphosphonate use, more safety data are needed.

THE “OLDER” SENIOR

Osteoporosis and adverse outcomes from fractures increase with age. Age is an independent risk factor for osteoporosis and osteoporotic fractures, with the prevalence increasing dramatically with age. Seniors are living longer. The average additional life span for an 85-year-old was 6.8 years in 2003 and it is estimated that the number of people in the United States age 85 years and older will increase from 5.1 million in 2004 to 7.3 million by 2020. The number of “older” seniors with osteoporosis is on the rise, yet the condition is vastly underdiagnosed and undertreated in this population.

Central DXA BMD testing is cost-effective in the older senior. If central DXA testing is not feasible (e.g., patient is institutionalized), heel or forearm testing using a portable quantitative ultrasound or peripheral DXA device can be used for risk stratification. Alternatively, calculation of the 10-year probability for hip or major osteoporotic fracture using FRAX can possibly be used.

Older seniors should practice a bone-healthy lifestyle, ingest adequate calcium and vitamin D, and implement measures to prevent falls. When deciding whether or not to use prescription medications in older seniors, the following factors need to be taken into consideration: remaining life span, ability to take and afford medications, cognitive function, GI disorders, polypharmacy, desire to avoid additional medications, and regimen complexity. Although efficacy and safety data are limited in the older senior, evidence consistently shows that those at highest risk for fracture benefit most from pharmacologic therapy.

GLUCOCORTICOID-INDUCED OSTEOPOOROSIS

Glucocorticoids are the most common secondary cause of osteoporosis and the third most common cause of osteoporosis overall. Approximately 30% to 50% of patients taking chronic oral glucocorticoids will experience a fracture. Bone losses are rapid, with the greatest decrease occurring in the first 6 to 12 months of therapy. Low to medium doses of inhaled glucocorticoids have no appreciable effect on bone density and fracture risk. The impact of long-term, high-dose inhaled glucocorticoids needs further evaluation.

The pathophysiology of glucocorticoid-induced osteoporosis (GIO) is multifactorial. Glucocorticoids decrease bone formation through decreased proliferation and differentiation, and enhanced apoptosis of osteoblasts. They can interfere with the bone’s natural repair mechanism through increased apoptosis of osteocytes, the bone’s communication cells. Glucocorticoids increase bone resorption by increasing RANKL and decreasing OPG. They can reduce estrogen and testosterone concentrations and create a negative calcium balance by decreasing calcium absorption and increasing urinary calcium excretion. The underlying disease processes might also contribute negatively to bone metabolism.

The 2001 American College of Rheumatology guidelines provide direction and are being updated. A baseline BMD using central DXA is recommended for all patients starting on 5 mg or more daily of prednisone equivalent for at least 6 months. BMD testing should also be considered at baseline in patients being started on shorter durations of systemic glucocorticoids if they are at high risk for low bone mass and fractures based on risk factors (e.g., age >65 years, postmenopausal, current smoker, and personal history of a
Patients undergoing solid-organ transplantation (e.g., kidney, lung, TRANSPLANTATION OSTEOPOROSIS
required. All patients starting or receiving long-term systemic osteoporosis. 123, 124 All patients using high-dose inhaled corticosteroids should be evaluated for low bone mass or repeated every 6 to 12 months if needed. Patients using high-dose corticosteroids for premenopausal women with hypogonadism. Bisphosphonate therapy is also recommended for patients starting or receiving long-term glucocorticoid therapy with documented low bone density (T-score < −1.0) or evidence of a low-trauma fracture. Teriparatide is the only anabolic therapy commercially available that increases bone formation. Teriparatide can be used if bisphosphonates are not tolerated or are contraindicated. Testosterone replacement therapy may be considered in men, and high-dose hormonal oral contraceptives for premenopausal women with documented hypogonadism.

TRANSMISSIONSTATION OSTEOPOROSIS
Patients undergoing solid-organ transplantation (e.g., kidney, lung, heart, and liver) have a high risk for osteoporosis and osteoporotic fractures. 125 Prior to transplantation, many patients have osteoporosis or low BMD because of osteoporosis risk factors (see Table 99–1) and negative bone effects from their underlying diseases (e.g., alcoholism, cachexia, impaired liver or kidney function, hypogonadism, and deconditioning) and medications (see Tables 99–2 and 99–3). After transplantation, bone loss and fracture risk increase dramatically within the first 6 to 12 months, mainly as a consequence of high-dose systemic glucocorticoid exposure and the use of calcineurin inhibitors (e.g., cyclosporine). Sometimes bone loss slows or improves within 1 year of transplant.

Before transplantation, patients should be evaluated for metabolic bone disease with lab tests and physical examination for secondary causes (see Tables 99–2 and 99–3), radiographs for vertebral fractures, and central DXA. 125 Regardless of BMD results, patients should be counseled on a bone-healthy lifestyle and instructed to take 1,000 to 1,200 mg of elemental calcium and 800 to 1,000 units of vitamin D daily to maintain sufficient concentrations. Calcitriol (1,25-dihydroxyvitamin D) at a dose of 0.5 mcg daily might be needed for renal and/or liver dysfunction. Pretransplant patients with osteoporosis or a low trauma fracture, except patients with end-stage renal disease awaiting kidney transplantation, should be started on bisphosphonate therapy. In patients with normal BMD prior to transplant, short-term bisphosphonate therapy (6–12 months) can be used to prevent bone loss after transplant. PTH has not been studied in the transplant population and is contraindicated in kidney transplant patients with secondary hyperparathyroidism. Testosterone replacement might be considered for men, and high-dose hormonal oral contraceptives are options for premenopausal women with hypogonadism. Central DXA can be repeated as early as 6 to 12 months to evaluate bone loss and the effects of treatment.

CHRONIC KIDNEY DISEASE
Chronic kidney disease is defined as kidney damage for at least 3 months with or without a decrease in glomerular filtration rate (GFR) or a GFR less than 60 mL/min/1.73 m² (0.58 mL/s/m²) for at least 3 months with or without kidney damage. In patients with a creatinine clearance (CrCl) greater than 30 mL/min (0.50 mL/s), osteoporosis can be managed routinely (see Fig. 99–3). As noted in FDA-approved product labeling, bisphosphonates are not recommended for patients with CrCl less than 30 or 35 mL/min (0.50 or 0.58 mL/s) because of potential drug accumulation. Newer data suggest that differences in the origin of chronic kidney disease, either intrinsic kidney damage or aging, might influence safety of these medications in those with age-related chronic kidney disease.

Based on large retrospective or pooled studies, oral bisphosphonates (CrCl as low as 15 mL/min [0.25 mL/s]), raloxifene (CrCl < 45 mL/min [0.75 mL/s]), and teriparatide (CrCl as low as 30–49 mL/min [0.50–0.82 mL/s]) appear safe and efficacious in patients with age-related declines in renal function. 126 Some experts recommend decreasing dose by 50% or extending the dosing interval, and using the agent for less than 3 years. 106 Renal osteodystrophy describes a constellation of metabolic bone disorders that develop in patients with stages 4 and 5 chronic kidney disease (GFR < 30 mL/min/1.73 m² [<0.29 mL/s/m²]) as a consequence of intrinsic kidney damage. Bone biopsy might be necessary to differentiate the different types of renal osteodystrophy from osteoporosis in this population. Antiresortive therapies would be appropriate for the management of osteoporosis; however, they are contraindicated in patients with osteomalacia or adynamic bone and may be ineffective for osteitis fibrosa cystica. 126

GASTROINTESTINAL DISEASES
The three most common gastrointestinal disorders associated with increased osteoporosis risk are inflammatory bowel disease, celiac disease, and postgastrectomy states. 27 Impaired absorption of key nutrients and minerals, chronic systemic glucocorticoid use, and increased levels of inflammatory cytokines are implicated. 128 The role of proinflammatory cytokines needs further investigation.

The prevalence of osteoporosis in patients with inflammatory bowel disease (e.g., Crohn’s disease or ulcerative colitis) ranges from 17% to 41%, and the relative risk for fracture is approximately 40% higher than that for the general population. 77, 238 When glucocorticoids are used, the GIO prevention and treatment guidelines should be followed. 129 Celiac disease is an inherited autoimmune disorder in which the ingestion of the protein gluten triggers an immune reaction that damages the mucosal lining of the small intestine and leads to impaired nutrient absorption. 129 Approximately 1% of the population has celiac disease, with women having twice the incidence of men. Low bone density is seen in up to 70% of patients with celiac disease. Long-term fracture risk is estimated to be double that of the general population. 77 Impaired nutrient absorption, especially calcium and vitamin D, plays a central role in the bone loss, requiring 25(OH) vitamin D monitoring. Celiac disease management requires a gluten-free diet, which can significantly increase BMD by approximately 5% within 1 year. 77, 130 Patients undergoing total or partial gastrectomy are at high risk for osteoporosis. The incidence of osteoporosis may be as high as 32% to 42% with a 30-year cumulative risk for fracture of 72% in women and 48% in men. 77 Although the pathophysiology of bone disease in postgastrectomy is unknown, reduced nutritional intake of protein might play a role. Bone density evaluation using central DXA should be considered in all patients who are more than 10 years postgastrectomy.
PHARMACOECONOMIC CONSIDERATIONS

The estimated burden for fractures in 2005 was $17 billion and is expected to increase to $25 billion by 2025. Consequently, determining who should be screened and treated for osteoporosis and fracture prevention is important. Various studies use different assumptions in their models.

Pharmacoeconomic considerations were used to determine 3% as the 10-year probability of hip fracture as a decision point in the NOF guidelines for which patients with low bone mass to treat. The value of $60,000 per quality-adjusted life-year was the cut point for cost-effectiveness. Sensitivity analysis was conducted for age, sex, and race/ethnicity, yielding similar results.

Preventing osteoporosis in postmenopausal women with normal or osteopenic BMD is not cost-effective. However, screening older women and only using a bisphosphonate for those with osteoporosis is cost-effective. The cost per quality-adjusted life-year decreased from $40,100 for women 65 to 74 years old to a cost savings for women 85 years old and older.

For men, screening and treating men after the age of 65 years with a low-trauma fracture and screening and treating men 80- to 85-years-old without a previous fracture were cost-effective when therapy costs were assumed to be $1,000 annually. With generic medications, screening at a lower older age in men might be warranted based on cost savings. In a different senior study, bisphosphonates were found to produce the greatest gain in quality-adjusted life-years at the lowest cost (i.e., $0.0637; $4,200), followed by PTH (0.0574; $6,833), calcitonin (0.0348; $5,761), and raloxifene (0.0339; $5,676).

EVALUATION OF THERAPEUTIC OUTCOMES

Besides monitoring for efficacy and safety, adherence evaluation should also be conducted.

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Central DXA BMD measurements can be obtained every 1 to 2 years for monitoring bone loss and every 2 years for assessing treatment response. In patients with conditions associated with higher rates of bone loss (e.g., glucocorticoid use), more frequent monitoring might be warranted.

To minimize test variability, BMD testing should be performed on the same DXA machine. A negative change in absolute BMD that exceeds the precision error of the machine at that site (approximately 3% for spine and 4% for hip) is considered a clinically significant BMD loss and warrants further investigation. Because changes in BMD do not entirely explain changes in fracture risk, many experts believe that decisions on whether or not to continue a particular therapy should not be based solely on BMD response.

Biochemical markers of bone turnover have been evaluated for use in monitoring early responses to medications, especially for identifying therapy nonresponders or possibly promoting adherence. Bone resorption markers, with the first or second morning void for urinary N-terminal crosslinking telopeptide of type 1 collagen or morning for serum C-terminal crosslinking telopeptide of type 1 collagen, are typically performed after an overnight fast at baseline and repeated after 3 to 6 months of therapy. These parameters will decrease with effective therapy. Circadian variability, seasonal variations, food intake, and recent exercise can all impact results. Because no consensus on result interpretation and high test variability exist, these tests are not yet considered routine.

PHARMACY SERVICES

Pharmacists play an important role in screening and monitoring for osteoporosis. Community pharmacy screenings with ultrasoundography identify patients who are at risk, and consultations with a pharmacist or other healthcare professional can increase lifestyle changes, medication use, and DXA referrals. This practice has been financially sustainable in the community pharmacy setting. Since adherence is strongly linked to fracture prevention, pharmacists should help identify and resolve medication-related problems that are affecting adherence for patients taking antosteoporotic medications.

Pharmacists can also increase use of these medications after a low-trauma fracture by using databases to identify undertreated patients. They can increase diagnostic testing and osteoporosis prevention/treatment, and identify and resolve medication and disease causes of bone loss, especially in special patient populations at greater risk.

OTHER METABOLIC BONE DISORDERS

Because of increased interest in bone diseases and newer medications, better therapies are being explored and developed for other bone diseases.

OSTEOMALACIA

Osteomalacia, meaning “soft bones,” is a condition seen in adults in which the bone is significantly undermineralized. Rickets is the childhood equivalent of osteomalacia. The most common cause of osteomalacia is severe, prolonged vitamin D deficiency. Disorders that cause hypophosphatemia and, rarely, medications such as long-term anticonvulsant therapy can also cause osteomalacia.

Patients with osteomalacia present with pathologic fractures and/or deep bone pain, proximal muscle weakness, or no obvious symptoms but low BMD. Patients with osteomalacia will have an extremely low 25(OH) vitamin D concentration (<10 ng/mL [<25 nmol/L]) and might have an elevated bone-specific alkaline phosphate and hypocalcemia. The treatment of osteomalacia caused by vitamin D deficiency is high-dose vitamin D replacement therapy. Prescription oral ergocalciferol 50,000 units once to twice weekly for at least 8 weeks is a regimen that is frequently used to raise vitamin D concentrations into the sufficient range. Other high-dose oral and intramuscular vitamin D regimens have also been used. Once 25(OH) vitamin D concentrations are greater than 30 ng/mL (75 nmol/L), chronic maintenance vitamin D therapy can be instituted. Oral ergocalciferol 50,000 units once or twice a month or nonprescription cholecalciferol at least 1,000 units up 2,000 units once daily are reasonable maintenance options.

PAGET’S DISEASE

Unlike osteoporosis, which is a systemic disorder affecting the entire skeleton, Paget’s disease is a disorder of bone remodeling in discrete sections of bone. The main areas affected are the skull, spine, pelvis, femur, and tibia. In this condition, the osteoclasts are abnormally large and have heightened activity, increasing the bone turnover rate and affecting both bone resorption and formation. The accelerated bone formation does not allow for proper layering of collagen, leading to disorganized or woven bone. The disease is usually asymptomatic; however, patients can experience bone pain, headaches with skull involvement, fractures, skeletal deformities, and, rarely, malignant transformation into osteosarcoma.
Paget’s disease tends to occur in adults 50 years and older, with a slight predominance in men and patients of north European ancestry.137 The disease affects approximately 1% to 2% of adults. Various environmental and genetic factors cause Paget’s disease, with viral causes a controversial pathogenesis. Paget’s disease is typically discovered because of an unexplained elevation in serum alkaline phosphatase or classic bone findings on routine x-ray films.

Bisphosphonates are the medication of choice for managing Paget’s disease because they work directly on osteoclasts to slow down bone turnover, allowing more time for proper bone formation.137,138 Six bisphosphonates are FDA indicated for the treatment of Paget’s disease. Calcium and vitamin D deficiencies need to be corrected before beginning bisphosphonate therapy. The most commonly used regimens are risedronate 30-mg tablet orally once daily for 2 months; pamidronate 60-mg intravenous infusion over 4 hours for 3 consecutive days; alendronate 40-mg tablet orally once daily for 6 months, and a one-time intravenous infusion of 5-mg zoledronic acid.

Zoledronic acid and risedronate regimens were compared in a head-to-head study, with zoledronic acid demonstrating a superior and more rapid and sustained therapeutic response.139 Demonstrated efficacy and convenience make zoledronic acid a good initial choice for most patients. Relapse after treatment is common (e.g., 28% in 5 years). Therapy can be repeated if symptoms return or serum alkaline phosphatase increases by 25% or more.

Subcutaneous or intramuscular salmon calcitonin is an approved option if bisphosphonate therapy is contraindicated. Analgesics, anti-inflammatory medications, and some forms of alternative healing might be needed to treat the pain symptoms.

CONCLUSIONS

Osteoporosis is a public health priority, as the prevalence of both the disease and fracture incidence is expected to increase in the next 10 to 20 years because of the increasing age of the population in many countries. Osteoporosis prevention begins at birth and continues throughout life by practicing a bone-healthy lifestyle (adequate calcium and vitamin D intake, exercise, no smoking, minimal alcohol use, and fall prevention). Generally osteoporosis occurs in postmenopausal women and senior men; however, the disease can occur in all ages as a result of secondary causes such as genetics, diseases, and medications. Portable ultrasonography machines can screen for osteoporosis but central bone densitometry (DXA) is used for diagnosis and monitoring.

Bisphosphonates are the medication class of choice because they decrease hip, nonvertebral, and vertebral fractures, are relatively safe, and are affordable. Teriparatide is the only medication that can build bone; however, cost and subcutaneous administration limit its use. Although medications decrease fracture risk, prescribing of antosteoporotic and preventive medications and adherence to such therapy is low. Suboptimal medication adherence is documented to decrease fracture prevention outcomes.

As osteoporosis management becomes more streamlined for postmenopausal women, practitioners are not only identifying other special populations at risk for osteoporosis (e.g., men, transplantation patients, glucocorticoid therapy, cancer therapies) but determining the best strategies for osteoporosis prevention and treatment. New agents and medication classes to prevent and treat osteoporosis show promise.

Other bone disorders, especially those related to vitamin D insufficiency and deficiency can be improved or eliminated with appropriate medications. Since most people are low in vitamin D, patients at risk for or with symptoms of bone disorders should have a 25(OH) vitamin D level drawn, with appropriate replenishment and maintenance vitamin D therapy instituted.

ADDENDUM

Denosumab was approved after this chapter was completed. Additional information includes serum calcium needs to be normal and major dental work should be completed before use. The product is a refrigerated prefilled pen that can be at room temperature up to 14 days before administration. Also available is a single use vial. Injection can be given in the upper arm, upper thigh, and abdomen.

Because of concerns about serious side effects, a medication guide, as part of the Risk Evaluation and Mitigation Strategy (REMS), is given to the patients. All providers are encouraged to participate in the an optional Postmarketing Active Surveillance Program to evaluate adverse effects. The prescriber can delegate this monitoring to other healthcare professionals, which could be a pharmacist including pharmacists.

REFERENCES

This page intentionally left blank
1 Rheumatoid arthritis (RA) is a systemic disease characterized by symmetrical inflammation of joints yet may involve other organ systems.

2 Control of inflammation is the key to slowing or preventing disease progression as well as managing symptoms.

3 Drug therapy should be only part of a comprehensive program for patient management which would also include physical therapy, exercise, and rest. Assistive devices and orthopedic surgery may be necessary in some patients.

4 Disease-modifying antirheumatic drugs (DMARDs) or biologic agents should be started within 3 months of the diagnosis of RA.

5 Nonsteroidal antiinflammatory drugs and/or corticosteroids should be considered adjunctive therapy early in the course of treatment and as needed if symptoms are not adequately controlled with DMARDs.

6 When DMARDs used singly are ineffective or not adequately effective, combination therapy with two or more DMARDs or a DMARD plus biologic agent may be used to induce a response.

7 Patients require careful monitoring for toxicity and therapeutic benefit for the duration of treatment.

Rheumatoid arthritis (RA) is the most common systemic inflammatory disease characterized by symmetrical joint involvement. Extraarticular involvement, including rheumatoid nodules, vasculitis, eye inflammation, neurologic dysfunction, cardiopulmonary disease, lymphadenopathy, and splenomegaly, can be manifestations of the disease. Although the usual disease course is chronic, some patients will enter a remission spontaneously.

**PATHOPHYSIOLOGY**

Chronic inflammation of the synovial tissue lining the joint capsule results in the proliferation of this tissue. The inflamed, proliferating synovium characteristic of rheumatoid arthritis is called **pannus**. This pannus invades the cartilage and eventually the bone surface, producing erosions of bone and cartilage and leading to destruction of the joint. The factors that initiate the inflammatory process are unknown.

The immune system is a complex network of checks and balances designed to discriminate self from non-self (foreign) tissues. It helps rid the body of infectious agents, tumor cells, and products associated with the breakdown of cells. In rheumatoid arthritis, this system no longer can differentiate self from non-self tissues and attacks the synovial tissue and other connective tissues.

The immune system has both humoral and cell-mediated functions (Fig. 100–1). The humoral component is necessary for the formation of antibodies. These antibodies are produced by plasma cells, which are derived from B lymphocytes. Most patients with RA form antibodies called **rheumatoid factors**. Rheumatoid factors have not been identified as pathogenic, nor does the quantity of these circulating antibodies always correlate with disease activity. Seropositive patients tend to have a more aggressive course of their illness than do seronegative patients. Immunoglobulins can activate the complement system. The complement system amplifies the immune response by encouraging chemotaxis, phagocytosis, and
Although it has been suggested that T cells play a key role in the pathogenesis of RA, B cells clearly have an equally important role. Evidence for this importance may be found in the effectiveness of B-cell depletion using rituximab in controlling rheumatoid inflammation. Activated B cells produce plasma cells, which form antibodies. These antibodies in combination with complement result in the accumulation of polymorphonuclear leukocytes, which release cytotoxins, oxygen free radicals, and hydroxyl radicals that promote cellular damage to synovium and bone. The benefits of B-cell depletion occur even though antibody formation is not suppressed with rituximab therapy suggesting other mechanisms play a role in reducing RA activity. B cells produce cytokines that may alter the function of other immune cells, and they also have the ability to process antigens and act as antigen-presenting cells, which interact with T cells to activate the immune process.  

In the synovial membrane, CD4⁺ T cells are abundant and communicate with macrophages, osteoclasts, fibroblasts and chondrocytes either through direct cell–cell interactions using cell surface receptors or through proinflammatory cytokines such as TNF-α, IL-1, and IL-6. These cells produce metalloproteinases and other cytotoxic substances, which lead to the erosion of bone and cartilage. They also release substances promoting growth of blood vessels and adhesion molecules, which assists in proinflammatory cell trafficking and attachment of fibroblasts to cartilage and eventual synovial invasion and destruction.  

Vasoactive substances also play a role in the inflammatory process. Histamine, kinins, and prostaglandins are released at the site of inflammation. These substances increase both blood flow to the site of inflammation and the permeability of blood vessels. These substances cause the edema, warmth, erythema, and pain associated with joint inflammation and make it easier for granulocytes to pass from blood vessels to the site of inflammation.

**Figure 100-1.** Pathogenesis of the inflammatory response. Antigen-presenting cells process and present antigens to T cells which may stimulate B cells to produce antibodies and osteoclasts to destroy and remove bone. Macrophages stimulated by the immune response can stimulate T cells and osteoclasts to promote inflammation. They also can stimulate fibroblasts which produce matrix metalloproteinases to degrade the bone matrix and produce proinflammatory cytokines. Activated T cells and macrophages release factors that promote tissue destruction, increase blood flow, and result in cellular invasion of synovial tissue and joint fluid. (APC, antigen-presenting cell; MMP, matrix metalloproteinase; IL, interleukin; TNF-α, tumor necrosis factor α.)

the release of lymphokines by mononuclear cells, which are then presented to T lymphocytes. The processed antigen is recognized by major histocompatibility complex proteins on the lymphocyte, which activates it to stimulate the production of T and B cells. The proinflammatory cytokines tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6 are key substances in the initiation and continuance of rheumatoid inflammation. Lymphocytes may be either B cells (derived from bone marrow) or T cells (derived from thymus tissue). T cells may be either CD4⁺ (T-helper) or CD8⁺ (cytotoxic or killer) T cells. There are two subtypes of T-helper cells: TH₁, which promote inflammation by producing interferon-γ, tumor necrosis factor, and IL-2; and TH₂, which produce the antiinflammatory cytokines IL-4, IL-5, and IL-10. In addition to TH₁-TH₂, a third type of T cell has been identified known as TH₃. It can produce IL-17. IL-17 can induce proinflammatory cytokines in fibroblasts and synoviocytes and stimulate the release of matrix metalloproteinases and other cytotoxic substances which leads to cartilage destruction. CD8⁺ killer T cells have a regulatory effect on the immune process by suppressing activity of CD4⁺ cells through release of antiinflammatory cytokines and promoting apoptosis (cell death). Activated T cells produce cytotoxins, which are directly toxic to tissues, and cytokines, which stimulate further activation of inflammatory processes and attract cells to areas of inflammation. Macrophages are stimulated to release prostaglandins and cytotoxins. T-cell activation requires both cell–cell interactions using cell surface receptors, called co-stimulation. One of these co-stimulation interactions is between CD28 and CD80/86. The binding of the CD80/86 receptor by abatacept has proved to be an effective treatment for RA but preventing co-stimulation interactions between T cells.

### CLINICAL PRESENTATION OF RHEUMATOID ARTHRITIS

**Symptoms**
- Joint pain and stiffness of more than 6 weeks’ duration. May also experience fatigue, weakness, low-grade fever, loss of appetite. Muscle pain and afternoon fatigue may also be present. Joint deformity is generally seen late in the disease.

**Signs**
- Tenderness with warmth and swelling over affected joints usually involving hands and feet. Distribution of joint involvement is frequently symmetrical. Rheumatoid nodules may also be present.

**Laboratory Tests**
- Rheumatoid factor (RF) detectable in 60% to 70%.
- Anticyclic citrullinated peptide (anti-CCP) antibodies have similar sensitivity to RF (50%–85%) but are more specific (90%–95%) and are present earlier in the disease.
- Elevated erythrocyte sedimentation rate and C-reactive protein are markers for inflammation.
- Normocytic normochromic anemia is common as is thrombocytosis.

**Other Diagnostic Tests**
- Joint fluid aspiration may show increased white blood cell counts without infection, crystals.
- Joint radiographs may show periarticular osteoporosis, joint space narrowing, or erosions.
On examination, the swelling of the joints may be visible or may be apparent only by palpation. The swelling feels soft and spongy because it is caused by proliferation of soft tissues or fluid accumulation within the joint capsule. The swollen joint may appear erythematous and feel warmer than nearby skin surfaces, especially early in the course of the disease. In contrast, the swelling associated with osteoarthritis usually is bony (caused by osteophytes) and infrequently is associated with signs of inflammation.

Involvement of the hands and wrists is common in RA. Hand involvement is manifested by pain, swelling, tenderness, and grip weakness during the acute phase and by subluxation, instability, deformity, and muscle atrophy in the chronic phase of the disease. Functional difficulties with clasp, grasp, and pinch alter both strength and fine motor movement.

Deformity of the hand may be seen with chronic inflammation. These changes may alter the mechanics of hand function reducing grip strength and making it difficult to perform usual daily activity.

The symptoms of RA usually develop insidiously over the course of several weeks to months. Prodromal symptoms include fatigue, weakness, low-grade fever, loss of appetite, and joint pain. Stiffness and muscle aches (myalgias) may precede the development of joint swelling (synovitis). Fatigue may be more of a problem in the afternoon. During disease flares, the onset of fatigue begins earlier in the day and subsides as disease activity lessens. Most commonly, joint involvement tends to be symmetrical; however, early in the disease some patients present with an asymmetrical pattern involving one or a few joints that eventually develops into the more classic presentation. Approximately 20% of patients develop an abrupt onset of their illness with fevers, polyarthritis, and constitutional symptoms (e.g., depression, anxiety, fatigue, anorexia, and weight loss).

No single test or physical finding can be used to make the diagnosis of RA. In early disease the diagnosis can be particularly challenging given that radiographic findings are usually not found and rheumatoid factor test can be undetectable. Duration of joint pain and swelling and morning stiffness lasting more than 1 hour and involvement of three or more joints are important early predictors of the development of persistent erosive rheumatoid arthritis.

JOINT INVOLVEMENT

The joints affected most frequently by rheumatoid arthritis are the small joints of the hands, wrists, and feet. In addition, elbows, shoulders, hips, knees, and ankles may be involved. Patients usually experience joint stiffness that typically is worse in the morning. The duration of stiffness tends to be correlated directly with disease activity, usually exceeds 30 minutes, and may persist all day. Chronic inflammation with lack of an adequate exercise program results in loss of range of motion, atrophy of muscles, weakness, and deformity.

On examination, the swelling of the joints may be visible or may be apparent only by palpation. The swelling feels soft and spongy because it is caused by proliferation of soft tissues or fluid accumulation within the joint capsule. The swollen joint may appear erythematous and feel warmer than nearby skin surfaces, especially early in the course of the disease. In contrast, the swelling associated with osteoarthritis usually is bony (caused by osteophytes) and infrequently is associated with signs of inflammation.

Involvement of the hands and wrists is common in RA. Hand involvement is manifested by pain, swelling, tenderness, and grip weakness during the acute phase and by subluxation, instability, deformity, and muscle atrophy in the chronic phase of the disease. Functional difficulties with clasp, grasp, and pinch alter both strength and fine motor movement.

Deformity of the hand may be seen with chronic inflammation. These changes may alter the mechanics of hand function reducing grip strength and making it difficult to perform usual daily activity.

The end results of the chronic inflammatory changes are variable. Loss of cartilage may result in a loss of the joint space. The formation of chronic granulation or scar tissue can lead to loss of joint motion or bony fusion (called ankylosis). Laxity of tendon structures can result in a loss of support to the affected joint, leading to instability or subluxation. Tendon contractures also may occur, leading to chronic deformity.

The symptoms of RA usually develop insidiously over the course of several weeks to months. Prodromal symptoms include fatigue, weakness, low-grade fever, loss of appetite, and joint pain. Stiffness and muscle aches (myalgias) may precede the development of joint swelling (synovitis). Fatigue may be more of a problem in the afternoon. During disease flares, the onset of fatigue begins earlier in the day and subsides as disease activity lessens. Most commonly, joint involvement tends to be symmetrical; however, early in the disease some patients present with an asymmetrical pattern involving one or a few joints that eventually develops into the more classic presentation. Approximately 20% of patients develop an abrupt onset of their illness with fevers, polyarthritis, and constitutional symptoms (e.g., depression, anxiety, fatigue, anorexia, and weight loss).
Pain in the elbow and shoulder may be the result of true joint inflammation or inflammation of soft-tissue structures such as tendons (tendonitis) or the bursa (bursitis). The knee also can be involved, with loss of cartilage, instability, and joint pain. Synovitis of the knee may cause the formation of a cyst behind the knee called a popliteal or Baker cyst. These cysts may become painful as they get tense, or they may rupture, producing a clinical picture similar to thrombophlebitis secondary to the release of inflammatory components into the area of the calf muscle (pseudothrombophlebitis syndrome). Chronic joint pain leads to muscle atrophy, which can result in a laxity of the ligamentous structures that support the knee, causing instability. Maintenance of an adequate range of motion of the knee is essential to normal gait.

Foot and ankle involvement in RA is common. The metatarsophalangeal joints are involved frequently in RA, making walking difficult. Subluxation of the metatarsal heads leads to “cock-up” or hammer toe deformities. Subluxation also may cause a flexion deformity at the proximal interphalangeal joint of the toe, leading to pressure necrosis of the skin over the joint secondary to irritation caused by shoes. Hallux valgus (lateral deviation of the digit) and bunion or callus formation may occur at the great toe. A widening of the foot occurs commonly with long-standing disease.

Involvement of the spine usually occurs in the cervical vertebrae; lumbar vertebral involvement is rare. Involvement of the first and second cervical vertebrae (C1–C2) can lead to instability of this joint. Patients with this problem are at a greater risk for spinal cord compression, although this complication is rare.

The temporomandibular joint (jaw) can be affected, resulting in malocclusion and difficulty in chewing food. Inflammation of cartilage in the chest can lead to chest wall pain. Hip pain may occur as a result of destructive changes in the hip joint, soft-tissue inflammation (e.g., bursitis), or referred pain from nerve entrapment at the lumbar vertebrae.

**EXTRAARTICULAR INVOLVEMENT**

Although joint involvement in RA is a hallmark finding in rheumatoid arthritis, it is important to recognize that, as a systemic disease, other organ systems are often involved.

**Rheumatoid Nodules**

Rheumatoid nodules occur in 20% of patients with RA. These nodules are seen most commonly on the extensor surfaces of the elbows, forearms, and hands but also may be seen on the feet and at other pressure points. They also may develop in the lung or pleural lining of the lung and, rarely, in the meninges. Rheumatoid nodules usually are asymptomatic and do not require any special intervention. Nodules are observed more commonly in patients with erosive disease.17

**Vasculitis**

Vasculitis usually is seen in patients with long-standing RA. Vasculitis may result in a wide variety of clinical presentations. Invasion of blood vessel walls by inflammatory cells results in an obliteration of the vessel, producing infarction of tissue distal to the area of involvement. Most commonly, small-vessel vasculitis produces infarcts near the ends of the fingers or toes, especially around the nail beds. These infarcts are usually of little consequence.

Vasculitis also may cause the breakdown of skin, especially in the lower extremities, producing ulcers that may be indistinguishable in appearance from stasis ulcers. However, these ulcers do not heal with the usual modes of treatment used for stasis ulcers.
Involvement of larger vessels with vasculitis can result in life-threatening complications. Infarction of vessels supplying blood to nerves can cause irreversible motor deficits. Involvement of vessels supplying other organ systems can lead to visceral involvement and a polyarteritis nodosa-like illness. Aggressive treatment of the inflammatory process is necessary in these patients. Fortunately, the more serious vasculitic picture is seen rarely.

Pulmonary Complications
Rheumatoid arthritis may involve the pleura of the lung, which is often asymptomatic, although pleural effusions may result. Pulmonary fibrosis also may develop as a result of rheumatoid involvement; smoking appears to increase the risk of this complication. Rheumatoid nodules may develop in lung tissue and appear similar to neoplasms on chest radiographs. Interstitial pneumonitis and artherosclerosis are rare, potentially life-threatening complications of RA.

Ocular Manifestations
Ocular manifestations include keratoconjunctivitis sicca and inflammation of the sclera, episclera, and cornea. Atrophy of the lacrimal duct may result in a decrease in tear formation, causing dry and itchy eyes, termed keratoconjunctivitis sicca. When this is observed in association with RA, it is referred to as Sjögren’s syndrome. Artificial tears may be used to relieve symptoms. The salivary glands may also be involved in Sjögren’s syndrome, resulting in dry mouth (xerostomia). Inflammation of the superficial layers of the sclera (episcleritis) is generally self-limiting. Involvement of deeper tissues (scleritis) usually results in a more serious, painful, and chronic inflammation. Rheumatoid nodules may develop on the sclera.

Cardiac Involvement
The heart is sometimes affected by RA. Rheumatoid arthritis is associated with an increased risk of cardiovascular mortality. This risk appears to be higher in those with more active inflammation and is reduced with treatment, particularly with methotrexate.18,19 Pericarditis may occur, resulting in the accumulation of fluid. Although many patients show evidence of previous pericarditis at autopsy, the development of clinically evident pericarditis with tamponade is a rare complication. Cardiac conduction abnormalities and aortic valve incompetence, caused by aortic root dilation, may occur. Myocarditis is a rare complication of RA.

Felty’s Syndrome
Rheumatoid arthritis in association with splenomegaly and neutropenia is known as Felty’s syndrome. Thrombocytopenia also may be a manifestation of the syndrome. Patients with Felty’s syndrome and severe leukopenia are more susceptible to infection. The decrease in granulocytes appears to be mediated by the immune system because splenectomy does not result in improvement of the patient.17

Other Complications
Lymphadenopathy may occur in patients with RA, particularly in nodes proximal to more actively involved joints. Renal involvement is rare but can be associated with treatment, including nonsteroidal antiinflammatory drugs (NSAIDs), gold salts, and penicillamine. Amyloidosis is a rare complication of longstanding RA. It appears to be more common in Europe than in the United States.

LABORATORY FINDINGS
Hematologic tests often reveal a mild to moderate anemia with normocytic, normochromic indices. The hematocrit may fall as low as 30%. The anemia is usually inversely related to inflammatory disease activity and is referred to as an anemia of chronic disease. This type of anemia does not respond to iron therapy and can present a diagnostic dilemma because NSAIDs may induce gastritis and chronic blood loss, leading to iron-deficiency anemia. Laboratory tests useful in differentiating these anemias include stool guaiac (or other stool tests for occult blood), serum iron-to-iron-binding capacity ratio (decreased in iron deficiency), ferritin (decreased in iron deficiency), and mean corpuscular volume (more likely to be decreased in iron deficiency). Other causes of anemia also must be considered in the differential diagnosis (see Chapters 109 and 111).

Thrombocytopenia is another common hematologic finding with active RA. Platelet counts rise and fall in direct correlation with disease activity in many patients. Thrombocytopenia may result from toxicity of immunosuppressive therapy. Thrombocytopenia also may be observed in Felty’s syndrome or vasculitis.

Although leukopenia is associated with Felty’s syndrome, it also may result from toxicity of methotrexate, gold, sulfasalazine, penicillamine, and immunosuppressive drugs. Leukocytosis is seen commonly as a result of corticosteroid treatment.

The erythrocyte sedimentation rate is usually elevated in patients with RA and other inflammatory diseases. This test is very nonspecific, and although the erythrocyte sedimentation rate usually falls as patients respond to therapy, there is a large variability among patients in response to treatment. C-reactive protein is another non-specific marker for inflammatory arthritis when it is elevated. This protein is produced by the liver in response to certain cytokines.

Rheumatoid factor is present in 60% to 70% of patients with RA. The usual laboratory test for rheumatoid factor is an antibody specific for immunoglobulin (IgM) rheumatoid factor. Patients with RA and a negative test for rheumatoid factor may have IgG or IgA rheumatoid factors, but tests for these are not routinely available. Rheumatoid factor tests may be reported positive at a specific serum dilution. Serum is diluted to a standard series of dilutions; the greatest dilution that yields a positive test result will be reported (e.g., rheumatoid factor positive at 1:640). Some laboratories quantify rheumatoid factor rather than using titers. Higher dilutional titers or serum concentrations of rheumatoid factors usually indicate a more severe disease, but like the erythrocyte sedimentation rate, the large interpatient variability makes this test unreliable as a means of assessing patient progress. Rheumatoid factor may be positive in patients without RA (Table 100–1).

Anticyclic citrullinated peptide antibody has similar sensitivity for RA, being found in 50% to 85% of patients with the disease, but is

more specific (90%–95%) and is detectable very early in the disease. Many rheumatologists will do both tests in evaluating new patients.

Antinuclear antibodies are detected in 25% of patients with RA. These antibodies usually have a diffuse pattern of immunofluorescence. Tests for antibodies to double-stranded DNA (usually positive in systemic lupus erythematosus) are negative. Serum complement is usually normal, although complement concentrations of joint fluid often are depressed from consumption secondary to the inflammatory process. In patients with vasculitis, serum complement concentrations may be low.20,21

Synovial fluid usually is turbid because of the large number of leukocytes in inflammatory fluid. White cell counts of 5,000 to 50,000/mm³ (5 × 10⁹ to 50 × 10⁹/L) are not uncommon in inflamed joints. The fluid is usually less viscous than that in normal joints or in fluid associated with osteoarthritis. Glucose concentrations of joint fluid are normal or low compared with those in serum drawn at the same time as synovial aspirates. The decrease is not as profound as the decrease associated with joint infection or systemic lupus erythematosus.

Early radiographic manifestations of RA include soft-tissue swelling and osteoporosis near the joint (periarticular osteoporosis). Joint space narrowing occurs as a result of cartilage degradation. Erosions tend to occur later in the course of the disease and usually are seen first in the metacarpophalangeal and proximal interphalangeal joints of the hands and the metatarsophalangeal joints of the feet. Periodic joint radiographs are a useful way of evaluating disease progression.

Seronegative Inflammatory Arthritis

Although RA may have a negative rheumatoid factor titer, a number of other systemic inflammatory arthritic conditions exist including psoriatic arthritis, reactive arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease. These conditions often tend to be less aggressive than what is typically seen with RA. Detailed discussion about these conditions is beyond the scope of this chapter, but further information may be found elsewhere.3 Management principles are similar to those for RA.

TREATMENT

Rheumatoid Arthritis

■ DESIRED OUTCOME

The primary objective is to improve or maintain functional status, thereby improving quality of life. Treatment of RA is a multifaceted approach that includes pharmacologic and nonpharmacologic therapies. Recent emphasis has been placed on aggressive treatment early in the disease course. The ultimate goal is to achieve complete disease remission, although this goal may not be possible to achieve in some patients. Additional goals of treatment include controlling disease activity and joint pain, maintaining the ability to function in daily activities or work, improving the quality of life, and slowing destructive joint changes.

■ NONPHARMACOLOGIC THERAPY

Rest, occupational therapy, physical therapy, use of assistive devices, weight reduction, and surgery are the most useful types of nonpharmacologic therapy used in patients with RA. Rest is an essential component of a nonpharmacologic treatment plan. It relieves stress on inflamed joints and prevents further joint destruction. Rest also aids in alleviation of pain. Too much rest and immobility, however, may lead to decreased range of motion and, ultimately, muscle atrophy, and contractures.

Occupational and physical therapy can provide the patient with skills and exercises necessary to increase or maintain mobility. These disciplines also may provide patients with supportive and adaptive devices such as canes, walkers, and splints.

Other nonpharmacologic therapeutic options include weight loss and surgery. Weight reduction helps to alleviate inflamed joint stress. This should be instituted and monitored with close supervision of a healthcare professional. Tenosynovectomy, tendon repair, and joint replacements are surgical options for patients with RA. Such management is reserved for patients with severe disease.22–24

■ PHARMACOLOGIC THERAPY

A disease-modifying antirheumatic drug (DMARD) should be started within the first 3 months of symptom onset (Fig. 100–5).22 Early introduction of DMARDs results in a more favorable outcome.25–30 NSAIDs and/or corticosteroids may be used for symptomatic relief if needed. They provide relatively rapid improvement in symptoms compared with DMARDs, which may take weeks to months before benefit is seen; however, NSAIDs have no impact on disease progression and the long-term complication risk of corticosteroids make them less desirable.28

Early treatment with DMARDs can reduce mortality. Patients with RA have increased mortality compared to people without the disease. In one trial, methotrexate reduced risk of mortality.29 Early treatment with DMARDs in patients followed for up to 10 years had mortality rates similar to patients without the disease.30

DMARDs including biologic agents should be used in all patients except those with limited disease. DMARDs commonly used include methotrexate, hydroxychloroquine, sulfasalazine, and leflunomide. The biologic agents that have disease-modifying activity include the anti-TNF drugs (etanercept, infliximab, adalimumab, certolizumab, golimumab), the costimulation modulator abatacept, and rituximab, which depletes peripheral B cells. Less frequently used are the IL-1 receptor antagonist anakinra, azathioprine, d-penicillamine, gold (including auranofin), minocycline, cyclosporine, and cyclophosphamide. This is due to either less efficacy, high toxicity, or both. The order in which the first-line agents are used is not clearly defined, although methotrexate is often chosen because long-term data suggests superior outcomes with methotrexate than with other DMARDs and a lower cost than biologic agents. Leflunomide appears to have similar long-term efficacy as that of methotrexate.32

The biologics have proven effective for patients who fail treatment with other DMARDs. Infliximab should be given in combination with methotrexate to prevent development of antibodies that may reduce drug efficacy or induce allergic reactions. Methotrexate

![FIGURE 100-5. Algorithm for treatment of rheumatoid arthritis using non-biologic DMARDs. Poor prognosis is defined as limitation in function, extra-articular findings (rheumatoid nodules, vasculitis, Felty syndrome, Sjögren syndrome, rheumatoid lung findings, erosions on radiograph). (DMARD, disease-modifying antirheumatic drug; MTX, methotrexate; NSAID, nonsteroidal antiinflammatory drug)](image_url)
in combination with other biologics is more effective than biologic monotherapy and the combination is frequently used.\(^{23}\)

Combination therapy with two or more DMARDs may be effective when single-DMARD treatment is unsuccessful.\(^{26,33–39}\) One study suggests that the initial combination therapy with either methotrexate, sulfasalazine plus prednisone, or infliximab plus methotrexate were superior to more conventional sequential monotherapy or step-up combinations of DMARDs in early rheumatoid arthritis.\(^{35}\) For patients with moderate to high disease activity, the American College of Rheumatology recommendations for nonbiologic and biologic DMARDs are dual DMARD combinations of methotrexate plus hydroxychloroquine, methotrexate plus leflunomide, or methotrexate plus sulfasalazine. They also recommend the triple combination of sulfasalazine, hydroxychloroquine, and methotrexate.\(^{23}\)

Corticosteroids can be used in various ways. They are valuable in controlling symptoms before the onset of action of DMARDs. A burst of corticosteroids can be used in acute flares. Continuous low doses may be adjuncts when DMARDs do not provide adequate disease control. Corticosteroids may be injected into joints and soft tissues to control local inflammation. Corticosteroids seldom should be used as monotherapy. There are data to suggest they have disease-modifying activity;\(^{35,36,40}\) however, it is preferable to avoid chronic use when possible to avoid long-term complications. NSAIDs and DMARDs have steroid-sparing properties that permit reductions of corticosteroid doses.

As immunosuppression may reduce the ability to mount an antibody response, the need for immunizations should be assessed, and these should be administered if needed before nonbiologic or biologic DMARDs are started.\(^{25}\) Postvaccination antibody titers seem to be only minimally affected by conventional DMARDs and TNF antagonists. Rituximab and abatacept seem to reduce the ability to develop antibodies after vaccination. Live vaccines are not recommended for patients taking biologic DMARDs.\(^ {41}\)

The American College of Rheumatology published recommendations for use of nonbiologic and biologic DMARDs in 2008. These recommendations are not intended to be prescriptive but provide guidance for treatment choice. Recommendations are given based on disease duration, degree of disease activity, and likely prognosis. The recommendations take into account barriers to treatment, including cost and insurance restrictions, by suggesting treatment options with and without expensive biologic treatments. Simplified algorithms summarizing these treatment recommendations are provided in Figures 100–5 and 100–6. For more details, see the published recommendation.\(^ {21}\)

### FIGURE 100-6. Algorithm for treatment of rheumatoid arthritis using biologic agents.

#### Nonsteroidal Antiinflammatory Drugs

NSAIDs should seldom be used as monotherapy for rheumatoid arthritis because they do not alter the course of the disease; instead, they should be viewed as adjuncts to DMARD treatment. NSAIDs possess both analgesic and antiinflammatory properties and reduce stiffness associated with RA. NSAIDs mainly inhibit prostaglandin synthesis, which is only a small portion of the inflammatory cascade. For details on these agents see Chapter 101, Osteoarthritis.

### Methotrexate

Methotrexate is now considered the nonbiologic DMARD of choice by many rheumatologists for treating RA. In psoriatic arthritis it not only treats the joint symptoms but also improves the skin disease for most patients. Methotrexate is contraindicated in pregnant and nursing women. It is also contraindicated in patients with chronic liver disease, immunodeficiency, pleural or peritoneal effusions, leukopenia, thrombocytopenia, preexisting blood disorders, and a creatinine clearance of less than 40 mL/min.

Absorption of methotrexate is variable and averages approximately 70% of an oral dose. Methotrexate is 35% to 50% bound to albumin; it may be displaced by highly protein-bound drugs such as NSAIDs, but the clinical importance of this interaction in the relatively low doses of methotrexate used in RA is unknown. Methotrexate is extensively metabolized intracellularly to polyglutamated derivatives. It is excreted by the kidney, 80% unchanged, by glomerular filtration and active transport. Some methotrexate may be reabsorbed, but this transport process may be saturated even with low doses, resulting in increased renal clearance.

Methotrexate inhibits cytokine production, inhibits purine biosynthesis, and may stimulate release of adenosine, all of which may lead to its antiinflammatory properties. The drug has a fairly rapid onset of action; results may be seen as early as 2 to 3 weeks after starting therapy. Some 45% to 67% of patients remain on methotrexate therapy in studies ranging from 5 to 7 years.\(^ {42,43}\) Methotrexate may be given intramuscularly, subcutaneously, or orally. Doses greater than 15 mg per week generally are given parenterally because of decreased oral bioavailability of larger doses.

The toxicities of methotrexate therapy are mainly gastrointestinal, hematologic, pulmonary, and hepatic. Stomatitis occurs in 3% to 10% of patients and may be painful or painless. Diarrhea, nausea, and vomiting may occur in up to 10% of patients. The most common hematologic toxicity is thrombocytopenia in 1% to 3% of patients. Leukopenia also may occur, but in a smaller number of patients. Although pulmonary fibrosis and pneumonitis can be severe adverse effects, they are rare.

Elevated liver enzymes may occur in up to 15% of patients; cirrhosis is rare. Liver function tests, aspartate aminotransferase or alanine aminotransferase, should be performed periodically. Methotrexate should be discontinued if these test values show sustained results greater than twice the upper limits of normal. An albumin blood level also should be checked periodically as a sign of liver toxicity because some patients may not have liver inflammation manifested by aspartate aminotransferase or alanine aminotransferase elevation. Liver biopsy is now recommended before beginning methotrexate therapy only for patients with a history of excessive alcohol use, ongoing hepatitis B or C infection, or recurring elevation of aspartate aminotransferase. Biopsies dur-

*Altered immune function increases infection which should be considered particularly in those patients taking azathioprine, methotrexate, and corticosteroids or other drugs as a symptom of myelosuppression.

**Osteoporosis is unlikely to manifest itself early in treatment, but all patients should be taking appropriate steps to prevent bone loss.

Leflunomide

Leflunomide is a DMARD that inhibits pyrimidine synthesis, leading to a decrease in lymphocyte proliferation and modulation of inflammation. It is given as a loading dose of 100 mg daily for 3 days, followed by a maintenance dose of 20 mg daily. Lower doses may be used if patients have gastrointestinal intolerance, complain of hair loss, or have other signs of dose-related toxicity. The loading dose allows the patient to achieve a more rapid therapeutic response, usually within the first month. The long elimination half-life of the drug (14–16 days) would require the patient to take the drug for several months to achieve steady state without a loading dose. Some rheumatologists prefer to begin with maintenance dosing as the loading dose may put the patient at increased risk for toxicity.

Leflunomide has efficacy similar to methotrexate for treating RA. The drug may cause liver toxicity and is contraindicated in patients with preexisting liver disease. Patients taking the drug should have alanine aminotransferase monitored monthly initially and periodically thereafter as long as they continue treatment. Leflunomide may cause bone marrow toxicity and complete blood count with platelets is recommended monthly for 6 months and then every 6 to 8 weeks thereafter.

The drug is teratogenic, and appropriate contraceptive measures are recommended to avoid pregnancy for all sexually active male and female patients who are taking leflunomide. If conception is desired, leflunomide must be discontinued. Because leflunomide undergoes enterohepatic circulation, the drug takes many months to drop to a plasma concentration considered safe during pregnancy (<0.02 μg/mL [≤0.02 mg/L; 74 nmol/L]). Cholestyramine may be used to rapidly clear the drug from plasma. In addition to pregnancy, cholestyramine use may be warranted to reduce drug levels in patients on other DMARDs, which simplifies monitoring. Short-term toxicities of hydroxychloroquine include gastrointestinal effects such as nausea, vomiting, and diarrhea, which can be managed by taking doses with food. Ocular toxicity includes accommodation defects, benign corneal deposits, blurred vision, scotomas (small areas of decreased or absent vision in the visual field), and night blindness. Although the risk of true retinopathy with hydroxychloroquine approaches zero, preretinopathy may occur in 2.7% of patients. All patients must understand the importance of adhering to hydroxychloroquine monitoring guidelines, as delineated in Table 100–2. Any visual change must be reported immediately. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.

Sulfasalazine

Sulfasalazine, a prodrug, is cleaved by bacteria in the colon into sulfapyridine and 5-aminosalicylic acid. It is believed that the sulfapyridine moiety is responsible for the agent’s antirheumatic properties, although the exact mechanism of action is unknown. Once the colonic bacteria have cleaved sulfasalazine, sulfapyridine and 5-aminosalicylic acid are absorbed rapidly from the gastrointestinal tract. Sulfapyridine distributes rapidly throughout the body, but higher concentrations are found in certain tissues such as serous fluid, liver, and intestines. Both sulfasalazine and its metabolites are excreted in the urine. Antirheumatic effects should be seen in 2 months.

Use of sulfasalazine is often limited by its adverse effects. Gastrointestinal adverse effects such as nausea, vomiting, diarrhea, and anorexia are the most common. These can be minimized by initiating therapy with low doses and titrating gradually to higher doses, dividing the dose more evenly throughout the day, or using extended-release preparations. This may delay the onset of action of hydroxychloroquine may be delayed up to 6 weeks, but the drug is considered a therapeutic failure only when 6 months of therapy without a response has elapsed.

The main advantage of hydroxychloroquine is the lack of myelosuppressive, hepatic, and renal toxicities that may be seen with other DMARDs, which simplifies monitoring. Short-term toxicities of hydroxychloroquine include gastrointestinal effects such as nausea, vomiting, and diarrhea, which can be managed by taking doses with food. Ocular toxicity includes accommodation defects, benign corneal deposits, blurred vision, scotomas (small areas of decreased or absent vision in the visual field), and night blindness. Although the risk of true retinopathy with hydroxychloroquine approaches zero, preretinopathy may occur in 2.7% of patients. All patients must understand the importance of adhering to hydroxychloroquine monitoring guidelines, as delineated in Table 100–2. Any visual change must be reported immediately. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.

Hydroxychloroquine

The pharmacokinetics of hydroxychloroquine are poorly understood. It is well absorbed orally and widely distributed to body tissues. Hydroxychloroquine is partially metabolized in the liver and is excreted by the kidney. The onset of action of hydroxychloroquine may be delayed up to 6 weeks, but the drug is considered a therapeutic failure only when 6 months of therapy without a response has elapsed.

The main advantage of hydroxychloroquine is the lack of myelosuppressive, hepatic, and renal toxicities that may be seen with other DMARDs, which simplifies monitoring. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.
enteric-coated preparations. Rash, urticaria, and serum sickness-like reactions can be managed with antihistamines and, if indicated, corticosteroids. If a hypersensitivity reaction occurs, therapy should be stopped immediately and another DMARD substituted. Sulfasalazine is associated with leukopenia, alopecia, stomatitis, and elevated hepatic enzymes. It also may cause the patient’s urine and skin to turn a yellow-orange color, which is of no clinical consequence however; patients should be educated about this to avoid premature discontinuance.

Sulfasalazine’s absorption can be decreased when antibiotics are used that destroy the colonic bacteria. Sulfasalazine also binds iron supplements in the gastrointestinal tract that can lead to a decreased absorption of sulfasalazine. The administration of these two agents should be separated temporally to avoid this interaction. Sulfasalazine can potentiate warfarin’s effects by displacing it from protein-binding sites. Close monitoring of the patient’s international normalized ratio is indicated.

Minocycline

The tetracycline derivative minocycline has been suggested as a treatment alternative for patients with RA who have low disease activity and without features of poor prognosis. A meta-analysis of 10 clinical trials using tetracyclines for more than 3 months found mild reductions in tender and swollen joint counts and erythrocyte sedimentation rate but no effect on erosion progression; however, the number of patients and treatment duration in the 2 trials that looked at erosions were limited.

The dose of minocycline in RA is 100–200 mg daily. Adverse effects are uncommon and were reported no more frequently than placebo control groups.

Other Disease-Modifying Antirheumatic Drugs

Gold salts, azathioprine, D-penicillamine, cyclosporine, and cyclophosphamide have all been used to treat RA. Although these drugs can be effective and they may be of value in certain clinical settings, they are used less frequently today because of toxicity, lack of long-term benefit, or both. Tables 100–2 and 100–3 provide dosing information and toxicity information.

Biologic Agents

Biologic agents are genetically engineered protein molecules that block the proinflammatory cytokines TNF-α (infliximab, etanercept, adalimumab, golimumab, and certolizumab), IL-1 (anakinra), and IL-6 (tocilizumab), deplete peripheral B cells (rituximab), or bind to CD80/86 on T cells to prevent the costimulation needed to fully activate T cells (abatacept). These drugs may be effective when other DMARDs fail to achieve adequate responses but are considerably more expensive to use. Other than anakinra and tocilizumab, these agents have no toxicity that requires laboratory monitoring, but they do carry a small increased risk for infection. There is an increased incidence of tuberculosis in patients treated with these agents. Tuberculin skin testing is recommended prior to treatment with these drugs so that latent tuberculosis can be detected.

Patients with a history of significant tuberculosis exposure or recurrent infection may not be good candidates for these drugs. Those who develop infections while on biologic agents should at least temporarily discontinue them until the infection is cured. Live vaccines should not be given to patients taking biologic agents.

TNF-α Inhibitors

Congestive heart failure (CHF) is a relative contraindication for anti-TNF agents. Increased cardiac mortality has been seen in patients treated with infliximab and etanercept-associated heart failure exacerbations have been documented. Patients with a history of uncompensated CHF or recent hospital admissions for CHF should not use anti–TNF-α therapy. Patients whose CHF worsens while taking anti–TNF-α therapy should discontinue the drug.
